rapidly develop fastness to streptomycin.² The bacilli in the urine in the case reported above—but not those in the peritoneal cavity—apparently developed such a resistance. Whether the bactericidal effect of the streptomycin is affected by the character of the medium in which it acts (peritoneal exudate as against urine) or whether the peritoneum wards off infection more readily than the urinary tract remains problematical. The rapid development of bacterial resistance against streptomycin and the great variability in its bactericidal action against various strains of the same organisms¹ suggest that large initial doses are advisable for effective and permanent sterilization.

SUMMARY

A case of colon-bacillus peritonitis that was successfully treated with streptomycin is reported, and certain pertinent points are discussed.

MEDICAL PROGRESS

ACTIVE IMMUNIZATION (Concluded)

GEOFFREY EDSALL, M.D.*

BOSTON

INFLUENZA

Following the identification of a virus agent causing human influenza,³¹⁴ efforts were made to develop vaccines effective in preventing or at least mitigating the infection. The finding of Burnet³¹⁵ that the fertile hen's egg provided a favorable medium for cultivating the influenza virus led ultimately to the use of this agent as the preferred culture medium. The demonstration that at least two distinct types of virus—designated "A" and "B"—could cause influenza^{316,317} posed the necessity of producing an effective bivalent vaccine. Numerous studies, usually with monovalent preparations, gave more or less equivocal results, whether the vaccine was administered subcutaneously³¹⁸⁻³²⁰ or by inhalation^{321,322}. There were occasional exceptions, as in the study by Henle et al.³²³ in which a striking degree

of protection was observed against influenza experimentally induced with a freshly isolated strain. A major improvement resulted from the discovery that the influenza virus could be efficiently concentrated by application³²⁴ of the chicken-cell-agglutination phenomenon observed by Hirst³²⁵ and McClelland and Hare,³²⁶ the preparation of virus suspensions of greatly increased immunizing potency being made possible. It had already been noted on occasion that vaccines of higher than average virus content appeared to give more promising results.³²⁰ Most of the succeeding studies, employing concentrated virus preparations,³²⁷⁻³³¹ produced higher immunity levels than had previously been attained, judged both by postvaccinal antibody titers and by resistance to natural or experimental infection.

Extensive confirmation of the value of a vaccine of this type was obtained in the study set up in 1943 under the Commission on Influenza, Army

*Director, Division of Biologic Laboratories, Massachusetts Department of Public Health; instructor in bacteriology and immunology, Harvard Medical School.

Use of impotent vaccine Smallpox vaccine is a living virus when properly prepared, and successful vaccination depends on the ability of this virus to multiply in the tissue of the vaccinated person. Multiplication of the virus in the host may fail for many reasons, including the following: improperly prepared vaccines (only by the practice of unceasing vigilance, even in a properly equipped and operated laboratory, is it possible to distribute a vaccine of consistently adequate potency, the operation of numerous small and inadequate vaccine establishments scattered through the Orient offers a possible explanation of the relatively frequent failure of vaccination seen in that part of the world³⁷⁰), improper storage of vaccine (vaccine virus, if refrigerated, lies dormant and retains its potency, but if allowed to warm up, it rapidly exhausts the metabolic resources of its suspending medium and dies, thus, failures to produce a successful reaction may be due to carrying the vaccine in the pocket or keeping it on a drugstore shelf—to be dependable, vaccine virus must have been stored at temperatures below freezing for as much of the time as possible, and the colder the temperature the better, since it is impossible to injure the virus by any available degree of cold), use of outdated vaccine (because it is usually not possible to keep smallpox vaccine continuously below 0°C at all times during shipping and handling, the vaccine necessarily undergoes some deterioration, and is therefore given a relatively short expiration date—for example, not over six weeks in Massachusetts—beyond which it cannot be regarded as dependable), and the use of less than the full contents of a capillary for each vaccination (this may result in failure, since on long standing the virus-laden lymph tends to separate from the clear glycerin portion, which is relatively inactive³⁷²).

Faulty vaccination technic A fully potent virus may fail to multiply in the vaccinated subject, because of any one of various errors in technic. Thus, the presence of such antiseptics as alcohol, mercurochrome and iodine on the vaccination site destroys the virus as soon as it is applied, and failure to achieve the right degree of penetration of the skin prevents the virus from obtaining a suitable site for multiplication. In a recent study in which two physicians used the same virus at the same time, one obtained twenty successful reactions out of twenty vaccinations, whereas the other obtained only six out of seventeen, the only difference being that the less successful physician failed to break the skin surface consistently with the needle.³⁷¹

Incorrect interpretation of the result obtained from vaccination A definite vesicle appearing at the site of vaccination is unmistakable evidence of a successful primary or accelerated reaction, but

the small papule characteristic of an immune reaction is less specific, and may be simulated by a traumatic reaction to the application of the needle. Furthermore, persons who have previously been vaccinated may exhibit a local allergic reaction to the antigenic substances in smallpox vaccine. A "dead" vaccine may thus induce a small papule, indistinguishable from an immune reaction except that it appears and disappears somewhat earlier.³⁷³ It is significant that the patients in the 23 cases of smallpox in the China-Burma-India Theater mentioned above were each recorded as having shown an immune reaction following vaccination, and similar experiences have been reported in the British Army in the Middle East.³⁷⁴ Indeed, Marsden³⁷⁵ says that the immune reaction should on no account be regarded as a successful result, since it does not necessarily indicate immunity, although often shown by immune subjects, and that persons who give this reaction but have histories that are at all uncertain should be vaccinated again and again. Marsden, however, acknowledges the validity of interpreting a deep-seated indurated swelling, developing about the third day and subsiding gradually, as a reaction of immunity.

Concerning the closely related subject of the person who cannot be vaccinated, d'Arcy et al.³⁷⁶ describe a hospital ship outbreak of 6 cases, in 5 of which the patients had recently been unsuccessfully vaccinated. Smith,³⁷⁷ the health officer meeting the ship at its first port of call, notes that in the prompt control of the outbreak, several persons were successfully vaccinated whose vaccinations had never previously been effective. One suspects that Dr. Smith was vigorous with the needle, indeed, it has repeatedly been recommended, particularly by British writers,³⁷⁸ that two or more insertions be employed whenever maximum protection against smallpox is urgent. Horgan and Haseeb³⁷⁹ have demonstrated, by the use of duplicate sites on previously vaccinated persons, that not all revaccinations produce the same result even under identical conditions at the same time, in their subjects the percentage of successful reactions, and hence the apparent ratio of accelerated to immune reactions, varied with the character of the virus preparation used. Nagler³⁸⁰ agrees with Horgan and Haseeb in recommending duplicate insertions on persons with a definite or probable history of previous vaccinations. It is worth noting at this point that a correlation between visible vaccination scars and resistance to smallpox in persons with histories of previous vaccination has been observed.³⁸¹ Some lay officials even require a visible vaccination scar as a basis for accepting a vaccination certificate.³⁸² This, of course, is unjustified, since vaccination by the multiple-pressure method usually leaves a scar that is subsequently difficult to find. The

cine of relatively short-lived effectiveness. It is to be hoped that from the experience of the armed forces a sufficient evaluation of allergic reactions to egg vaccines will have accumulated to determine at least tentatively the significance of such reactions. The possibility of employing eggs from ducks or turkeys, as suggested by Berkowitz³⁵⁰ for typhus vaccine, should be further explored.

Numerous modifications of the liquid concentrated allantoic fluid vaccine have been tried. Precipitation with alum³⁵¹ or protamine³⁵² did not appear to enhance the potency materially, whereas a vaccine suspended in oil^{347, 353} by Freund's method³⁵³ induced a rather high incidence of untoward local reactions. Salk³⁵⁴ has recently applied a technic long employed in potentiating antigens used in animal immunization, by adsorbing the vaccine virus on calcium phosphate, with preliminary results that appear promising. Such measures may prove particularly satisfactory when combined with improved methods of concentrating and purifying the virus. The differential centrifugation developed by Stanley³⁵⁵ appears to be highly effective, and further information on the alcohol-concentration method of Tovarnizky³⁵⁶ is awaited with interest. Improved means of inactivating the vaccine with minimal injury to its antigenic potency, such as the use of ultraviolet irradiation,^{346, 356} may further enhance the efficacy of the vaccine.

All the advances outlined above merely serve to increase the immunizing potency of the currently available egg-adapted strains of influenza virus. Burnet³⁵⁷ showed that egg adaptation is accompanied by fundamental changes in the biologic properties of the virus, and a far larger body of evidence than is now available will be required to determine whether such a modified antigen can retain its clinical effectiveness as well as the vaccinal modification of smallpox virus. Evidence already indicates that the influenza virus strains in current use for preparation of vaccines are antigenically somewhat apart from those isolated in recent epidemics.^{356, 358} Likewise, apparent antigenic differences between prevalent epidemic strains have been demonstrated.^{358, 359} The observations of Beveridge and Burnet,³⁶⁰ Shope³⁶¹ and others, however, suggest that, by selection of appropriate strains or by repeated vaccination, immunity of a broader antigenic pattern than that induced by single injections of the currently available vaccines is possible. It is well to bear in mind that the exact etiology of the influenza pandemic of 1918 is still unknown and, in all probability, will never be determined. No one can predict with assurance — although Shope³⁶¹ has made a brilliant approach to this problem — what the biogenesis of the next epidemic will be, and one is left to ponder the following still appropriate editorial comment³⁶² of three years ago:

Spectacular as have been the advances in recent years in research in influenza, it cannot be said that, faced with a disaster such as that of 1918, we are yet in a position to do anything very dramatic in order to prevent its spread. The virus responsible for the next pandemic will almost certainly be one that is unrelated to those now isolated. For this reason it will be necessary first to isolate the virus. This in itself may be a difficult proceeding, for a susceptible animal will first have to be found. Even supposing this proved to be possible, the manufacture of vaccine in sufficient time for use in the epidemic is — by all present indications — a sheer impossibility. And vaccines compounded from known strains will almost certainly be useless.

SMALLPOX

The continuing importance of maintaining adequate smallpox immunity, wherever one may be, is attested by reports such as that of the Hongkong epidemic of 1937-1938, in which 2000 persons died,³⁶³ of the Glasgow outbreak of 1942, which, although nipped in the bud, killed 24 per cent of those infected,³⁶⁴ of 5 deaths among 23 cases in American troops in the China-Burma-India Theater³⁶⁵ and of the recent outbreak of virulent smallpox in Seattle, imported by American troops returning from the Orient. One still occasionally hears the claim that the reduction in smallpox, where it has been achieved, is the result of improved sanitation. Rogers³⁶⁶ has outlined the fallacy of this argument so far as India is concerned, where decreases in smallpox morbidity are observed side by side with an unchanged prevalence of such diseases as cholera. Nor is it pertinent to claim that present-day smallpox is mild and therefore unimportant, for it is well established that the mild and severe forms may alternate in successive epidemics or coexist in the same one. Finally, the relation between the incidence of smallpox and the extent and effectiveness of vaccination laws has been so conclusively shown^{367, 368} that space will not be taken here to repeat the evidence.

The shifting populations of the recent war years have provided a fertile soil for transmission of smallpox and have put current vaccination programs and methods to a rigorous test. Although several incipient epidemics of smallpox resulting from these conditions were readily checked by vaccination, the small number of failures reported may serve as a basis for critical consideration of the requirements that must be met to achieve successful vaccination. In any such consideration it must again be emphasized that no immunization procedure is absolutely effective. The causes of vaccination failures can nevertheless for the most part be itemized, as follows:

Long interval since vaccination. The occurrence of smallpox in persons not vaccinated for many years merely points by contrast to the effectiveness of vaccination in persons also exposed who, having been vaccinated more recently, are found to be clearly protected.³⁶⁹

eruption," which in turn is indistinguishable from eczema vaccinatum, can arise from infection with the virus of herpes simplex⁴⁰⁵⁻⁴⁰⁷ Thus eczema vaccinatum should be regarded as a syndrome arising basically from eczema rather than from vaccination. Hershey and Smith⁴⁰⁸ point out the desirability of dropping the older clinical designations quoted above, specifying instead the virus and the underlying cutaneous disease, if any.

Although far rarer than generalized vaccinia, postvaccinal encephalitis is still observed occasionally in Europe and rarely in this country. Seven cases, 2 of which were fatal, were reported following some five hundred thousand vaccinations in the Edinburgh area in July, 1942.⁴⁰⁹ In Fife, on the other hand, 9 cases were observed in seventy-three thousand vaccinations.⁴¹⁰ Thus the incidence continues to vary tremendously in different series, in this country it can scarcely be greater than 1 in two hundred thousand. In dealing with such a rare condition, when the diagnosis is at best made by inference and when several known and no doubt several other unknown etiologic agents may induce a virtually indistinguishable picture, it is difficult to arrive at any significant conclusions. Although cases in infants do occur,^{411 412} the incidence is probably not over 1 in eight million.⁴¹¹ Moreover, encephalitis is extremely rare after revaccination.⁴¹¹ Hence it could probably be rendered even rarer by primary vaccination in infancy, which is also to be preferred for many other reasons. Treatment with convalescent serum has been used^{412 413} but is subject to the limitations mentioned under generalized vaccinia.

Postvaccinal tetanus has virtually been eliminated since the role of vaccination dressings, bunion pads, contaminated bone points and other factors in the etiology of this complication has been publicized. Nevertheless, the disregard of such well founded precautions is still occasionally followed by tetanus.⁴¹⁴ Miscellaneous complications continue to be related to vaccination from time to time,⁴¹⁵⁻⁴¹⁷ but without substantial evidence that the relation is more than coincidental.

RABIES

Any attempt to evaluate antirabic vaccination on the basis of available experimental or epidemiologic evidence is somewhat inconclusive, as shown in the extensive review by Webster⁴¹⁸ and compactly summarized recently by Casals.⁴¹⁹ The lack of extensive convincing evidence for the efficacy of rabies vaccine in preventing experimental animal infection was formidably exposed in Webster's thirteen-page table summarizing such experiments. Moreover, the epidemiologic data cited by Webster — derived chiefly from McKendrick⁴²⁰ — certainly do not provide any conclusive proof that antirabic vaccination protects human beings from the disease. Nor is there any comfort in the finding of

Denison and Dowling⁴²¹ in Alabama that rabies occurs with approximately equal frequency among Whites, who often seek antirabic treatment, and Negroes, who rarely apply for such treatment. Furthermore, these authors point out that among the 48 human deaths from rabies in the seventeen-year period considered, 23 occurred in persons judged to have received prompt and adequate treatment. They conclude that there is little relation between mortality from rabies and the administration of vaccine. On the other hand, the findings of Palik and Moss⁴²² that the mortality rate in treated persons was greater following bites from proved as against unproved rabid animals, from head bites as against bites elsewhere and in Negroes as against Whites, could be equally well explained by the assumption either that the vaccine gave only a partial protection or that it gave no protection whatsoever. Only their finding (confirmed by McKendrick's much larger series of cases) that delay beyond fourteen days in seeking treatment markedly increases the risk of death from rabies gives support to the belief that rabies vaccine is of value in human beings.

Such data, however, are by their very nature inconclusive. They may be influenced by a great variety of uncontrollable but highly important factors. First among these is the actual rarity of human rabies, 48 cases of any disease over a seventeen-year period,⁴²¹ for example, scarcely provide statistically significant data. Also, multitudinous factors influence the chances of infection: location of the bite, depth of the bite, entrance of saliva into the wound (as affected, for example, by clothing), local treatment applied, interval before seeking local or systemic treatment and so forth. Since such factors are always present in human exposure to rabies and since it will always be virtually impossible to obtain a properly controlled and statistically significant series of untreated cases, the evaluation of antirabic vaccination by epidemiologic methods must remain an unsatisfactory approach, and results based on this approach must be judged accordingly.

Regardless of statistical data, the experience of years has firmly established the belief, among all who have studied the problem, that antirabic vaccination greatly reduces the chances of contracting rabies. Webster,⁴¹⁸ after reviewing the lack of evidence for the efficacy of the vaccine, proceeds to furnish a detailed and elaborate schedule of the indications for vaccine treatment. And despite the fact that rabies is rare (no human case having occurred in Massachusetts, for example, since 1935), the disease is so horrifying to most minds and death from it is so absolutely certain that people continue to demand and physicians to administer the vaccine, with its attendant discomforts and risks, rather than face even a remote prospect of succumbing to rabies. It has little practical bearing on the case that most people think nothing of daily

responsibility must remain with the physician, to ensure that nothing less than a clear-cut immune reaction is observed before permitting a patient to risk exposure to smallpox.

Variations in the host-parasite relation. These can involve differences in vitality or specificity of the vaccinia virus employed, in the infectivity of the strain of smallpox encountered, and in individual response to the immunizing process. It is difficult to believe that 20 out of a group of 62 subjects exhibiting successful primary reactions could have manifested such reactions not more than fifteen months earlier, as reported by Minning,³⁸³ unless there were a qualitative difference in the two strains of vaccinia virus used. Stevenson,³⁷⁸ on the other hand, is inclined from analogy with animal studies to believe that the differences in protection observed following vaccination are due to differences in the immune response of the host. Evidence for such a concept is not readily adduced, but fairly convincing evidence has recently been presented that vaccinia virus strains of completely unrelated origin provide approximately equivalent protection against a virulent endemic strain of smallpox.³⁸⁴ For practical purposes, it is therefore wise to follow the simple dictum of d'Arcy³⁷⁸ that it is only the successful vaccination that counts, to persist in vaccinating until a successful vaccination is achieved, and to revaccinate at intervals of five to seven years and whenever vaccination is otherwise indicated.

Little can be said regarding the optimum age for vaccination, since few observations on this point have been made. Ratner⁴ offers the reasonable statement that the ideal time for vaccination is between three and six months of age and cites data regarding neonatal vaccination, mostly confirming the general impression that successful reactions at this age are undependable. It is almost universally agreed, chiefly for reasons given below, that vaccination should be performed not later than the first year of life.

At present virtually all smallpox vaccine available is prepared by inoculation on calves, carabao, sheep or similar herbivora, but the virus can be successfully cultivated in tissue media³⁸⁵ and the chorioallantoic membrane of the chick embryo.³⁸⁶ Vaccines have been prepared by both methods. Results with tissue-culture vaccine (inoculated intradermally) have been poor, the immunity being apparently quite transitory,^{387, 388} perhaps owing to an insufficient concentration of virus in the material employed. Chick-embryo vaccine has given promising results in the hands of several workers,^{379, 380, 389} is being employed on a limited scale in this country and elsewhere, and is strongly favored in principle by some investigators. One study with egg vaccine in this country indicated that the material employed induced a substandard immunity

and a deeper than average tissue reaction at the site of vaccination. Nagler³⁹⁰ on the contrary, observed that the reaction induced is more superficial than that produced by calf vaccine, and that immunity depends largely on the virus content, regardless of the source of the virus. One may safely predict that chick-embryo vaccine will be used on a much larger scale in the future, unless allergic reactions to vaccines derived from hen's eggs³⁴⁹ prove to be an obstacle.

Intracutaneous vaccination, as employed by Rivers and others^{387, 388} has been tried in the hope that immunity could be achieved without the necessity of producing a cutaneous vesicle. Results with chick-embryo virus given by this route have been little better than those with tissue-culture material.³⁹⁰ Even less promising were the results obtained with a formalinized vaccine.³⁹¹

Combinations of smallpox vaccine with other immunizing agents are rare, Blanchard³⁹² has reported the use of a mixed yellow-fever and smallpox vaccine. Combined immunization with smallpox and typhoid vaccines is a curiosity that has been reported by a Japanese,³⁹³ as one might almost expect—incidentally, the only modern report of peranal immunization for any purpose is also from Japan.³⁹⁴

Reactions, in a small percentage of persons vaccinated, continue to be reported from time to time. Autoinoculation on various body sites may occur in vaccinees,³⁹⁵⁻³⁹⁷ and is also occasionally observed among workers in contact with smallpox vaccine at this laboratory and elsewhere.^{398, 399} Thirty-four mild and miscellaneous skin eruptions were observed among two hundred and seventy-four thousand vaccinations in the Edinburgh outbreak.³⁹⁵ Several types of rashes occur, varying from a local erythema of greater or less extent that is a constant accompaniment of successful vaccination to lesions that embrace either the affected arm or other parts of the body⁴⁰⁰ and even to generalized vaccinia. Whether generalized vaccinia is to be distinguished from eczema vaccinatum is debatable, the excellent reviews of Jubb⁴⁰¹ and of McKhann and Ross⁴⁰² offer detailed discussions. The incidence of this complication is variously reported, but English and American figures⁴⁰¹⁻⁴⁰³ indicating that there is about 1 case in forty thousand vaccinations are representative. Since most cases appeared in eczematous patients and the mortality rate was disturbingly high prior to the advent of the chemotherapeutic drugs, it has been universally recommended that persons with eczema be protected from any contact with vaccinia virus, either direct or indirect, except when exposure to smallpox is likely. Treatment with convalescent serum has been employed⁴⁰⁴ but is of extremely doubtful value in this as in all other virus diseases. Furthermore, the syndrome is not always due to the vaccine virus. Recent case reports demonstrate that Kaposi's so-called "varicelliform

evidence on which this procedure is based and showed that, in experimentally infected guinea pigs, irrigation with a 20 per cent solution of soft soap is as effective as chemical cauterization with fuming nitric acid — and possibly even more effective. The administration of rabies vaccine is usually carried out in one of the following situations: a definite bite by a proved rabid animal, a definite bite by an animal in which rabies cannot be excluded — either the animal was lost track of or pathological examination was inconclusive, and any definite bite on the head or neck — treatment should be given while the animal is being observed and suspended if the animal is well seven days after the bite.

No general agreement exists regarding the possible channels of infection, besides definite skin-penetrating bites, that require treatment. Such situations may vary so widely that they are not subject to generalizations but must be considered individually.

Reactions to rabies vaccine have been reviewed by McKendrick⁴²⁰ and summarized by Webster⁴¹⁸ and Casals.⁴¹⁹ In slightly over a million treatments, major paralytic accidents occurred in 181 subjects (1 in 5861), and 48 were fatal (1 in 22,100). Neurologic complications were more frequent following the use of attenuated virus vaccines than with vaccines prepared from killed virus (1 in 3398 as against 1 in 8887). This supports the theory that such reactions are due to traces of viable and infective fixed virus. Kelser⁴⁴⁴ suggests that their occurrence with the use of phenolized (Semple) vaccine may be explained by the ability of phenol to coagulate proteins, so that occasional units of viable virus are left within a coagulated particle. Whatever the explanation, the occasional occurrence of these complications is sufficient contraindication to the administration of antirabic treatment unless there are clear-cut indications for its use.

risking death (or, what is sometimes worse, survival) from spinal-cord injury or skull fracture following an automobile accident. Rabies remains a fear-inspiring menace in the mind of man, and will continue to do so whenever the possibility of contracting the disease exists.

Many of the inconclusive results reported following antirabic treatment were undoubtedly due to the use of ineffective vaccines. It is only within the last few years, beginning with Webster's development of a mouse test for measuring the immunizing potency of rabies vaccine,⁴²³ that evaluation of such vaccines and directed efforts toward their improvement have become practical. This method, which was found by others to provide a valid basis for distinguishing between potent and impotent batches of vaccine,⁴²⁴ was further developed by Habel⁴²⁵⁻⁴²⁷ and is included in the minimum requirements for rabies vaccine established recently by the National Institute of Health.⁴²⁸ Concurrently, various studies have been in progress on the improvement of rabies vaccines. Hodes et al.⁴²⁹ showed that an effective vaccine could be obtained from rabies-infected tissue inactivated by ultraviolet irradiation, and an improvement on this principle has been developed by Levinson et al.⁴⁷³ Meanwhile, Webster and Casals⁴³⁰ had made the not unexpected finding that the potency of a rabies-vaccine preparation depended to a large extent on its virus content. This finding has been confirmed,^{427 431 432} and probably explains the relatively high efficacy of Kelser's chloroform-killed dog vaccine,⁴³³ which contains a much larger amount (33 per cent) of brain and cord tissue than is ordinarily used. Furthermore, several investigators have found differences in the effective or immunizing properties of various strains of fixed virus^{426, 434} suggesting the importance of proper selection of strains for vaccine production. Hence, the prospects are that the quality of rabies vaccines available hereafter will be both superior to and more consistent than that of the vaccines of the last fifty years.

Further evidence of protection against rabies has been forthcoming in experimental and field use of the vaccine in dogs. A few years ago it was authoritatively stated that "as yet there is no authentic or convincing evidence that would lead to the belief that successful antirabic vaccination for dogs is available."⁴³⁵ However, Leach and Johnson,^{431 436} Damon⁴³² and others demonstrated that a good vaccine provides excellent protection against experimental infection, that a poor grade of vaccine provides only moderate protection and that unvaccinated control animals have a significantly greater fatality rate than the vaccinated groups. Furthermore, the field results are impressive. Beginning in 1937, over 6000 dogs a year have been vaccinated in Montgomery County, Alabama, simultaneously with a much less extensive program for disposal of stray dogs. The animal rabies incidences in this

county from 1936 to 1943, respectively, were 74, 23, 29, 0, 1, 0, 0 and 1. On the other hand, Mobile County, where dog vaccination was opposed, exhibited a continuously high incidence of animal rabies throughout this period.⁴³⁷ Experience in Massachusetts has been similar, although less extensive. Because the state laws make effective dog quarantine virtually impossible, a dog-vaccination campaign was begun in 1934 and stressed particularly in communities in or near areas reporting animal rabies. Either because of these inoculations or because of the natural rhythm in the rise and fall of the disease, cases of rabies in animals have declined since 1934, as indicated by the following figures:⁴³⁸

YEAR	NO OF CASES	YEAR	NO OF CASES
1930	310	1938	58
1931	304	1939	39
1932	131	1940	73
1933	171	1941	31
1934	331	1942	20
1935	278	1943	5
1936	136	1944	1
1937	211	1945	0

Dog vaccination, therefore, appears to furnish a promising means of controlling the principal reservoir of the disease. Occasionally, when rabies becomes seeded in wild animals,^{439 440} vigorous, specific eradication measures are highly effective in clearing up such foci. By and large, however, in a country such as the United States, where the disease cannot be kept out as in Australia and Hawaii, or eradicated as in England and Scandinavia, the best available measure for its suppression lies in building up the resistance of the dog population. Vaccination clearly does not provide a dog with absolute protection, but it does appear to increase the resistance sufficiently so that the minimal infective dose of virus is increased, and hence only the deeper bites, or those with an exceptionally high virus content, manage to infect. It has been pointed out by Anderson⁴⁴¹ for rabies, and by many others for diphtheria and other diseases, that if the frequency of transmission of a disease is reduced below a certain level, the disease tends to die out of itself. This is the rationale of continuing and extending the program of antirabies dog vaccination recommended by the Massachusetts Department of Public Health. Such a program must, for obvious reasons, go hand in hand with the elimination of stray dogs, some of the attendant problems of dog control and the ways in which they may be successfully surmounted have recently been pointed out by Hewitt.⁴⁴²

The decision whether to administer rabies vaccine depends on a number of factors, and there are many different recommendations regarding the exact rules to follow. It is universally recommended that the wound be cauterized with nitric acid. Shaughnessy and Zichis,⁴⁴³ however, questioned the

CASE 32361

PRESENTATION OF CASE

A sixty-year-old housewife entered the hospital because of hematuria.

The patient was apparently well until three months before entry, when she fell, fracturing the left wrist. Following this accident she had a bout of painless hematuria, with the passage of small dark clots two or three times a day for three days. There was no concurrent frequency, urgency or other urinary symptoms. She remained asymptomatic until twenty-four hours before entry, when she suddenly passed bright-red blood while straining to urinate. During the night she urinated at hourly intervals, with some dysuria and difficulty in starting the stream. There was no incontinence, costovertebral-angle pain, chills or fever. She had had no previous urinary symptoms, and there was no recent weight loss, change in bowel habits or melena.

Twenty years before entry the patient had a tumor "filled with water" removed from the right lower quadrant of the abdomen. Seven years before entry, following a period of weakness, weight loss and slight postmenopausal bleeding, a hysterectomy was performed at a local hospital. She was not called back for a follow-up and received no x-ray treatment. She had had no vaginal bleeding since this operation. The menopause occurred fifteen to twenty years before entry.

On physical examination the heart and lungs were negative. There was slight tenderness in the suprapubic region. Pelvic examination revealed a second-degree perineal laceration and slight tenderness in the region of the bladder.

The temperature, pulse, and respirations were normal. The blood pressure was 160 systolic, 90 diastolic.

Examination of the blood showed a red-cell count of 5,050,000, with 90 per cent hemoglobin, and a white-cell count of 19,700, with 88 per cent neutrophils. The nonprotein nitrogen was 35 mg, and the total protein 6.5 gm per 100 cc. The chloride was 98 milliequiv per liter, and the carbon dioxide

26.9 milliequiv. The urine was grossly bloody and gave a +++ test for albumin.

Cystoscopy showed dark-red blood oozing from the right ureteral orifice. Clear urine was discharged from the left ureter. On the posterior wall of the bladder, in the midline and extending up to the dome and to the right, was a red, thickened area of mucosa covered by a layer of whitish slough or fibrin. A 3-mm papillary mass was seen in the center of this area. Several biopsy specimens from this lesion were reported as showing acute and chronic inflammation.

An intravenous pyelogram showed no excretion of dye on the right side over a period of sixty minutes. The left kidney was small and excreted the dye promptly. The bladder contained lobulated filling defects having the appearance of blood clots. There were multiple small calcifications in the spleen. A retrograde pyelogram showed obstruction of the right ureter 6 cm above the ureteral vesical junction, where there was a caplike defect in the upper margin of the dye (Fig 1). A plain film of the abdomen showed a large soft-tissue mass in the pelvis that reached to the level of the fourth lumbar vertebra and was consistent with a distended bladder; there were several dilated loops of small bowel. An x-ray film of the chest showed a considerable amount of fibrosis throughout both lung fields and two rounded areas of increased density in the left lung field.

The patient had several episodes of acute urinary retention and intestinal distention. An operation was performed on the eleventh hospital day.

DIFFERENTIAL DIAGNOSIS

DR. J. DELLINGER BARNEY: The fact that this patient had an episode of painless hematuria lasting for two or three days following a relatively minor fall may mean either that the fall was not so insignificant or that it lighted up some quiescent lesion in the kidneys or bladder. The absence of accompanying frequency, urgency or other symptoms tends to eliminate an inflammatory process. On the other hand the return of the hematuria some twenty-four hours after the initial episode, this being accompanied by considerable frequency, with dysuria and difficulty in starting the stream, suggests some inflammatory process arising subsequent to the injury. The absence of costovertebral-angle pain, chills and fever seems to rule out, or at least to decrease, the possibility of definite kidney infection.

Going on to the next item, the tumor "filled with water," which the patient said was removed twenty years before entry, may have been an ovarian cyst or something malignant, although the length of time that had elapsed since the operation rather tends to remove the latter possibility. The history of a hysterectomy seven years before entry for vaginal bleeding associated with symptoms of loss

matory tissue cannot be avoided. I do not believe that the calcification seen in the spleen is of any particular significance.

The important observation, however, was that in trying to do a retrograde pyelogram definite obstruction in the right ureter at a level of 6 cm above the ureteral orifice was found. May I see the films?

DR. MILFORD D. SCHULZ: The films show non-visualization of the right kidney because of an obstruction in the lower portion of the right ureter, which is shown on attempted retrograde filling. The catheter apparently would not pass beyond the lowermost 6 cm of the ureter, where an irregular filling defect is lined by opaque material injected through the retrograde catheter. This has the appearance of a ragged non-opaque defect, possibly a polypoid soft-tissue mass, blood clot or stone. The soft-tissue mass seen arising from the pelvis on one film seems to be a distended bladder. Many defects in the visualized bladder are transient and are probably blood clots. The areas of density mentioned in the chest films may be metastases, but they are not too impressive.

DR. BARNEY: The record does not state whether any urine was obtained from the right kidney. The so-called "cap-like defect" in the dye that was injected into the right ureter may have been due to a variety of things. It may have been caused by a simple stricture, which was associated with more or less dilatation of the ureter. It may have been due to stone, which was either non-opaque or slightly so. It may have been caused by a neoplastic growth.

The films of the abdomen, which are said to show a large soft-tissue mass, may have indicated a neoplastic growth with adherent loops of small bowel or a full bladder. I am not able to interpret the various areas of density seen in the twenty-minute film of the bladder, especially the two or three that are just to the left of the midline. These may represent areas of calcification, either within the bladder or outside it. On the other hand they may be small collections of dye in the sacculi or folds of the lesion seen by cystoscopy. I do not believe, however, that these areas of density represent calcification. The films of the chest show fibrosis, and the two round areas of increased density in the left lung field may represent either tuberculosis or metastatic cancer.

I am not able to throw much light on the episodes of acute urinary retention and intestinal distention that occurred before operation. Again, however, all this may have been due to the fact that there was malignant disease outside the bladder in the pelvis, with adhesions between loops of small bowel and with a splinting, one might say, of the bladder so that it could not empty itself in the normal manner.

In looking over all these facts about the case I think one can say that the initial episode of hematuria originated in a lesion already existing in the bladder before the fall that the patient sustained. The onset of urinary symptoms, such as the dysuria and the difficulty in starting the stream, together with the nocturia, suggests a rather long-standing process in the bladder. I think that a kidney lesion can be ruled out, owing to the absence of the usual

FIGURE 2

kidney symptoms, such as pain and tenderness. The fact that there was no recent weight loss or change of bowel habits does not necessarily rule out cancer. I do not believe that the abdominal tumor removed twenty years before entry had anything to do with the present situation. I do, however, think that the hysterectomy, together with the history of weakness, loss of weight and vaginal bleeding, is suggestive of cancer of the uterus. The cystoscopic find-

of weight and weakness suggests malignant disease of the uterus, but the patient might have had fibroids

The white-cell count of the blood was considerably elevated, with a rather abnormal number of polymorphonuclears. The bloody urine was consistent with the history, and it is unfortunate that nothing

bladder strongly suggest a sloughing and infiltrating neoplasm, which was either primary or an extension from some other source. I say this in spite of the fact that several biopsy specimens showed only acute and chronic inflammation. It is possible that, together with the inflammatory tissue, there was neoplastic tissue. The statement that the intra-

FIGURE 1

more than blood and albumin was reported. One would like to know whether there were pus cells or bacteria. The fact that cystoscopy showed dark blood coming from the right ureteral orifice seems to limit the source of bleeding to the right kidney or ureter. Also, the clear urine coming from the left kidney, together with the x-ray appearances of a normal kidney on the left side, appears to eliminate the left kidney as a source of the hematuria. The conditions described on the posterior wall of the

venous pyelogram showed no dye on the right side in a period of sixty minutes indicates that the kidney was either entirely absent or was badly diseased. The lobular filling defect in the bladder, which was thought to suggest blood clots, is interesting but does not necessarily contribute anything more than the cystoscopic findings. The lesions seen in the bladder and shown by x-ray may, in fact, have been organized adherent blood clots, but the possibility of neoplasm or inflam-

lymphatic vessels or whether there was bacteremia, followed by pyelitis

During the patient's stay in the hospital the abscess increased in size, the temperature rose, and an operation was performed on the fifth hospital day. The sequence of infection, peritonitis, localization and abscess is quite clear cut. One is left with the problem of determining the cause of the infection that initiated this series of events.

The history gives several leads: the patient was known to have had ulcerative colitis, the onset of the illness coincided with the beginning of menstruation, and with the preceding period a less severe attack had occurred. Ulcerative colitis usually bears no relation to menstruation, at the time of menstruation, however, any chronic condition may be aggravated, and there is retention of water and swelling of the pelvic organs. Partial obstruction of the diseased bowel may therefore have followed, with perforation and the development of an abscess. Against this explanation is the fact that there was no real exacerbation of the colitis. Perforation due to ulcerative colitis occurs during an acute stage of the disease.

Perforation of the bowel due to a foreign body, such as a piece of wire or a pin, often occurs in the region of the ileocecal valve, but there is nothing in the history to suggest such a possibility. Carcinoma of the cecum may perforate and give a similar picture.

Because of the radiation of the pain upward and around the flank, kidney or ureteral difficulty should be considered. Carbuncles of the kidney do not point in this direction, and stones in the ureter rarely cause abscesses, so that any genitourinary process that developed must be considered secondary to an intraperitoneal infection.

The most frequent cause of right lower-quadrant discomfort — followed in a month by a severe attack and abscess formation — is acute appendicitis with perforation. The location of this abscess was typical of one of appendiceal origin, and the history was consistent with appendicitis. On a statistical basis this case can best be explained as acute appendicitis with perforation.

Acute cholecystitis, perforating peptic ulcers and acute pancreatitis cause right lower-quadrant abscesses, but there is little in the history to suggest any of these conditions.

The fact that the pain coincided with the onset of the last two menstrual periods is stressed. This may have no significance, but it may be a lead in discovering the cause of the abscess. Infection in or around the tube or ovary, which often flares up at the time of menstruation, could account for this clinical picture. The abscesses of pelvic inflammation often

localize in the right lower quadrant. Against this possibility is the statement that the patient was entirely well between the attacks of pain. The radiation of the pain is also against pelvic inflammation. Endometriosis, with secondary infection, is a rare condition that might have accounted for the abscess in this case.

My diagnosis is a right lower-quadrant abscess that was most probably secondary to an acute appendicitis.

DR LELAND S MCKITTRICK: When I saw this patient in consultation at the hospital, I could not be at all certain of the diagnosis. I thought that I could feel a mass in the lower abdomen, but I was not certain because of the slight distention and the well marked tenderness. There seemed every reason to suppose that the ulcerative colitis was not responsible for this particular episode. If there was an abscess it was believed that there was everything to gain and nothing to lose by avoiding immediate operation. The patient was much better on the following day, the distention subsided, gas was freely passed by rectum, and as the abdomen softened the mass was easily palpated. At the time of operation the diagnosis was ovarian cyst with a twisted pedicle. Pelvic abscess secondary to a ruptured appendix was the second choice.

CLINICAL DIAGNOSIS

Ovarian cyst, with twisted pedicle

DR INGERSOLL'S DIAGNOSIS

Ruptured appendix with pelvic abscess

ANATOMICAL DIAGNOSIS

Dermoid cyst of ovary, with torsion and infarction

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: Dr McKittrick's operative note was as follows:

A small, right muscle-splitting incision was made, the intention being to open into any abscess that was present or to permit a diagnosis if an abscess was not encountered. When the peritoneal cavity was opened a dark mass was presented having the physical characteristics of an infarcted tumor. The incision was then enlarged, and the adherent small bowel was carefully freed. The entire mass, which proved to be an ovarian cyst with one complete rotation of the pedicle, was then freed from the abdominal wall and surrounding structures. It was removed without difficulty. No further exploration was carried out.

The specimen we received was an obviously infarcted ovarian cyst measuring 12 by 8 by 5 cm. The wall was quite thick, and the lumen was filled with the characteristic sebaceous material and hair

ings indicate a lesion rather low down in the right ureter, and in the absence of stone or any evidence of a simple stricture, I think that this patient had a carcinoma of the ureter on the right side, probably metastatic from carcinoma of the uterus, with extension into the bladder. This may have accounted for the soft-tissue mass in the pelvis that was reported by the radiologist, but I confess that this finding does not impress me too much.

CLINICAL DIAGNOSIS

Carcinoma of ureter

DR. BARNEY'S DIAGNOSIS

Carcinoma of ureter, right, with extension into bladder (? metastatic from uterus)

ANATOMICAL DIAGNOSIS

Papillary carcinoma of ureter, right.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN The operation consisted of a right ureteronephrectomy. The ureteral obstruction, which had produced a moderate hydronephrosis, proved to be a grayish-yellow friable obviously carcinomatous mass 4 cm in length involving the entire circumference of the ureter and apparently completely occluding its lumen (Fig. 2). The wall was invaded, but the serosa was perfectly smooth. Microscopically it was a papillary carcinoma of the transitional type of epithelium that normally lines the ureter and bladder. There was no extrinsic tumor, and no involvement of the bladder. The defects seen in the bladder were almost certainly blood clots, because when the patient was last seen two months post-operatively, the bladder looked perfectly normal.

Papillary tumors of the renal pelvis and ureter have been known to implant in the bladder, although there still is some question whether the bladder lesions are implants or autonymous growths. Personally I am inclined to favor the latter thesis.

quadrant, with nausea and vomiting that lasted three days. The ache disappeared when the period ceased, and the patient was well until six days before admission, when the next period started. Five days before admission she noticed in the right lower quadrant a slight ache that within twenty-four hours developed into a severe pain, radiating around the right flank and up toward the right costal margin. She was nauseated, vomited frequently and was unable to retain anything by mouth for three days. The day before admission she felt better and retained some fluid. On the day of admission the pain was less severe and there was no vomiting. No stools or flatus had been passed for four days.

The abnormal findings on physical examination were confined to the abdomen and pelvis. The abdomen was distended, and there were moderate spasm and acute tenderness in the right lower quadrant. Rebound tenderness was referred to the right. There was a questionable mass in the right lower quadrant. Peristalsis was normal. Pelvic examination revealed acute tenderness in the right vault.

The temperature was 101.5°F, the pulse 108, and the respirations 22. The blood pressure was 110 systolic, 70 diastolic.

Examination of the blood showed 13 gm of hemoglobin and a white-cell count of 23,400, with 90 per cent neutrophils. The urine gave a ++ test for albumin, and the sediment contained 40 white cells, with frequent clumps, and 6 red cells per high-power field. The nonprotein nitrogen was 15 mg per 100 cc, and the prothrombin time 27 seconds (normal, 22 seconds).

The patient's condition remained unchanged. Dysuria developed on the second day, and there was gross blood in the urine. The temperature fell to 99°F, where it remained until the fourth hospital day, when it rose to 101.5°F. The white-cell count ranged between 19,000 and 25,000. The mass in the right lower quadrant became more definite and slightly larger.

An operation was performed on the fifth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. FRANCIS INGERSOLL The outstanding fact in this case is that a septic process developed. The onset was acute and severe, and the symptoms of peritonitis rapidly developed. Fortunately, this process was localized, and when the patient was admitted on the sixth day of her illness an abscess was present in the right lower quadrant and pelvis. The elevation of the white-cell count to 23,400, with 90 per cent neutrophils, indicates an excellent response to this infection. An abscess located over the course of the ureter may lead to urinary infection with dysuria and pyuria, which were present in this case. There is no indication of whether the infection invaded the urinary tract by extension through the

CASE 32362

PRESENTATION OF CASE

A forty-three-year-old housewife entered the hospital complaining of pain in the right lower quadrant of the abdomen.

The patient had had ulcerative colitis for about twelve years, with many remissions and exacerbations. The last episode of active colitis took place seven months before admission, when she was hospitalized for three weeks for study and treatment. After discharge she remained well until a month before admission. Coincident with the onset of the menstrual period there was an ache in the right lower

materials and more suitable ones will undoubtedly become available as time goes on and will probably be of the greatest help in working out many of the difficult but fundamental biologic problems that can best be solved through the use of such tracer materials. One can also look forward to considerable advances in the therapeutic use of radioactive materials.

"HIS ACTS BEING SEVEN AGES"

DR. MARJORY W. WARREN,¹ in a recent issue of the *Lancet*, has presented the case of the chronic aged sick, in whom, so often, "dull, apathetic, helpless and hopeless, life lingers on sometimes for years, while those round them whisper arguments in favour of euthanasia." This is not the picture that should be presented, nor will it be when we fully awaken to our responsibilities, which are new in their present magnitude. The aged infirm we have always had with us, but owing largely to the triumphs of medicine, the span of life has steadily lengthened, and because of the war and the entrance of women into industry, there is a shortage of young persons available to care for the aging population.

The better care of the chronic sick, and particularly the aged sick, is a medical responsibility that will in no wise decrease with time, for the expectation of life is constantly improving. Thus, in Great Britain the population of persons aged sixty or over has increased from less than 2,500,000 in 1901 to over 6,250,000 in 1944, and in the United States it is estimated that the 9,000,000 population of those sixty-five years of age or over in 1940 will increase to 22,000,000 in 1980. Since we have succeeded in prolonging human life, we must bend our energies to making that prolongation endurable. There is little doubt that the infirmities of age have been neglected and that too little effort has been made to diagnose and treat the illnesses of old people and to plan for what degree of rehabilitation may be found possible and practicable.

The aged, in their hospitalization, need wards that are designed to meet their physical circumstances, that simulate their accustomed surroundings and that are near their homes. They need diets suited to their age, and equipment adapted to their infirmities.

They need floors that are not highly polished, hand-rails about their wards and elevators or suitably graded stairways. The geriatric hospital ward should be used as a clearinghouse to the patient's or to an otherwise suitably conducted home, with a close and continuing follow-up. Never should the patient, regardless of age, who can be salvaged for whatever time is remaining be allowed to become bedridden.

Geriatrics should be as useful a specialty for the latter end of life as pediatrics is for the beginning years. In the words of the editorial² accompanying Dr. Warren's paper, "Given domestic help, nursing care and medical attention when needed, many old people who now die after years in hospital could live interesting and possibly useful lives at home, finally dying triumphantly in their own beds."

MASSACHUSETTS MEDICAL SOCIETY BUREAU OF CLINICAL INFORMATION

All secretaries of various medical groups, such as special societies and alumni associations, are requested to notify the Bureau of Clinical Information regarding scheduled meetings, annual dinners and so forth. If such data are on file, it is hoped that duplication of dates can be avoided.

DEATHS

HARPIN — Raymond A. Harpin, M.D., of Lynn, died August 10. He was in his forty-third year.

Dr. Harpin received his degree from Boston University School of Medicine in 1931. He was a fellow of the American College of Surgeons.

His widow survives.

HOWLAND — George L. Howland, M.D., of Jamaica Plain, died August 7. He was in his seventy-seventh year.

Dr. Howland received his degree from Tufts College Medical School in 1897. He was a fellow of the American Medical Association.

LEE — Harry J. Lee, M.D., of Boston, died August 7. He was in his sixty-sixth year.

Dr. Lee received his degree from Boston University School of Medicine in 1904. He was a member of the staffs of the Newton, Cambridge and Hahnemann hospitals and the New England Hospital for Women and Children. He was a fellow of the American College of Surgeons and the American Medical Association.

His widow and two sons survive.

REID — I. Eugene Reid, M.D., of Jamaica Plain, died August 12. He was in his seventy-third year.

Dr. Reid received his degree from the University of Edinburgh Faculty of Medicine in 1897. He was a fellow of the American Medical Association.

His widow, a son and a daughter survive.

ATOM BOMB AND MEDICAL RESEARCH

AS IN the case of other projects undertaken primarily for the conduct of war, many significant and far-reaching peacetime developments can be expected to result from the knowledge and materials acquired in the course of producing the atom bomb. Numerous developments of interest to biologists and to medical investigators will undoubtedly result from the fact that certain radioactive isotopes are now available in sufficient quantities for use in fundamental researches. Valuable contributions to physiology and therapeutics have already evolved as a result of the use of such isotopes produced in relatively small quantities with the cyclotron. The use of radioactive iodine in the treatment of thyrotoxicosis by Hertz and others and the studies of Ross and Gibson and their associates with radio-

active iron are examples of local contributions made possible with the materials and methods developed by Evans, Roberts and others at the Massachusetts Institute of Technology.

Those in charge of the Manhattan Project* have recently made a detailed announcement concerning the isotopes that will be available and the mechanism by which investigators may obtain them. It was pointed out that the production of tracer and radiotherapeutic isotopes is one of the great peacetime contributions of the uranium chain-reaction pile. Since the inception of the pile, these men have been cognizant of its peacetime potentialities, and since the end of the war, they have been active in attempting to realize these opportunities. Since, however, the war-built piles and wartime researches had other objectives, a considerable transition in developments and operations connected with the piles must be effected before the supply of radioactive isotopes can begin to meet the demand.

The limitation of the pile in making available pure radioactive substances must be emphasized. Most of the products being made available are not salvaged by-products of the plutonium process but are items requiring special production from processed irradiated uranium. In particular, the majority of the radio isotopes in greatest demand in biology and medicine, such as those of carbon, sulfur and phosphorus, must be produced by irradiation of materials that are foreign to the existing piles, which were not designed for this purpose.

Special committees have been set up and policies have been temporarily established for the distribution of materials as they become available. The chief criterion to be used in their distribution is the maximum benefit to the national welfare considering the limited amounts of radioactive isotopes that are on hand. They are to be distributed to individuals only through qualified institutions and organizations, which will be responsible for their proper use. Charges for the additional costs incurred in filling these requests will be made to the institutions in which they are used.

A list of the supplies of the various materials on hand and their properties was published. Additional

resistant to sulfonamide therapy.⁵ The Department of Public Health has therefore voted to discontinue distribution of antimeningococcus serum. In conjunction with this change in policy, it is desirable to recapitulate the principal considerations in the treatment of suspected or proved cases of meningitis.

Diagnosis Treatment of meningitis varies according to the causative organism, specimens of cerebrospinal fluid and blood for bacteriologic examination must therefore be obtained before therapy is begun. The importance of early and accurate bacteriologic diagnosis has recently been summarized in the *Journal*.⁶

Drug therapy In any case of meningitis in which purulent fluid is obtained by lumbar puncture, it is advisable to administer penicillin. This drug should always be given to such patients intrathecally as well as intramuscularly.

Sulfonamides (sulfadiazine, sulfamerazine and sulfathiazole) are of definite value in the treatment of meningitis caused by the pneumococcus, streptococcus or *Haemophilus influenzae* (Pfeiffer bacillus) and are the agents of choice in the treatment of meningococcal infections. Early and adequate sulfonamide therapy (by mouth, or parenterally as the sodium salt, but not intrathecally) is therefore indicated in any case of meningitis pending bacteriologic diagnosis.

Precautions Because patients with meningitis are usually dehydrated as a result of vomiting, fever, sweating and failure to take fluids, it is essential to precede the first administration of any sulfonamide drug by the administration of fluids, given preferably by the intravenous or the subcutaneous routes and in sufficient amounts to overcome the dehydration. *Regardless of the sulfonamide drug selected or the route of administration, ample fluid output should be ensured by whatever means is most effective.* It is also advisable to administer sodium bicarbonate or lactate to prevent the precipitation of sulfonamides in the kidneys.⁷ Observance of these principles will help to avert complications, which otherwise frequently arise.⁸

Specific therapy When a bacteriologic diagnosis is established, specific therapy is recommended as follows, the agents being given in the order of preference.

Meningococcus Sulfadiazine, penicillin

Streptococcus Penicillin and sulfadiazine

Pneumococcus Penicillin, sulfadiazine and typhoid-specific antipneumococcus serum.*

H. influenzae (Pfeiffer bacillus), Type B Streptomycin, sulfadiazine and anti-*H. influenzae*, Type B, serum*, all three in combination

CORRESPONDENCE

AN UNUSUAL FOREIGN BODY

To the Editor: Dr. Miller's report of a rose stalk in a boy's neck, in the August 1 issue of the *Journal* recalls a somewhat similar case that occurred during my internship at Worcester City Hospital more than forty years ago.

A middle-aged Polish laborer was admitted to the Accident Room with a punctured wound of the right buttock. The patient's command of English, as well as that of the friends who accompanied him, being extremely limited, no history could be elicited except that "a stick had hit him." He complained of some pain but was otherwise in good condition. The wound was explored by the finger, but since no foreign body could be felt, it was believed to be a simple puncture. He was, however, kept for observation. On the third day he developed hematuria, on the fifth day signs of general peritonitis appeared, from which he died in a few days.

Autopsy showed a piece of wood over an inch in diameter that had entered through the right sacrospinous notch, transfixing the bladder and reached the obturator foramen on the left. Both ends were firmly fixed, and the pathologist was obliged to saw it to dislodge it from its position. It was blunt at both ends.

Later investigation showed that the patient had been working on some sort of wood-working machine when a large splinter flew off and entered his body, an extraordinary instance of centrifugal force.

BOOK REVIEWS

The Biological Basis of Individuality. By Leo Loeb, M.D. 8°, cloth, 711 pp. Springfield, Illinois: Charles C. Thomas, 1945. \$10.50.

In this excellent book the author takes the position that it was necessary for one person to undertake this work, rather than to edit a collective book written by specialists in the different sciences that contribute the essential data; he appears to have succeeded admirably well in his effort. The subject is considered a mosaic of many tissues and organs, each functioning and metabolizing in its own peculiar way. The particular characteristic distinguishing one subject from another is designated as individuality differential. The author finds transplantation experiments best suited to analyzing differences as expressed in terms of individuality.

Individuality differentials on the one hand and organ and tissue differentials on the other are supported by references to comparative anatomy, embryology, genetics and biochemistry. The problems are discussed under the headings of transplantation of tissues in higher organisms, which furnishes the most delicate tests of individuality differentials, phylogenetic and ontogenetic development of individuality and organismal differentials, from the primitive to the highest organisms and from the egg to the adult state, conditions suggesting or simulating the presence of individuality differentials that exist in certain unicellular organisms, organismal differentials of tumors, which represent modified

MEDICOLEGAL ABSTRACT

Relation of Patient and Physician Liability for malpractice. The plaintiff entered the hospital in September, 1942, for rest and treatment for a nervous condition and other ailments brought about principally by acute gall-bladder attacks.

He was advised to consult the defendant, who gave him an electric shock treatment. On September 21, the defendant administered a second shock treatment. When the plaintiff recovered consciousness, he was suffering from severe pain in the right hip and thigh. This was called to the defendant's attention, but he ignored it until September 24, when x-ray examination showed a fracture of the right hip.

The plaintiff sued for negligence in the administration of the shock treatment and for negligence in the diagnosis.

At the trial the plaintiff presented no evidence other than that from which the above stated facts could be found. The defendant offered only the testimony of a doctor whom he sought to qualify as an expert on shock treatment. This witness had been an orthopedic surgeon for thirty years and had treated two hip fractures and one shoulder fracture resulting from shock treatment. He had also seen one spinal fracture resulting from shock treatment. He stated that he was familiar with the literature and reports of the medical profession on shock treatment and had talked with various specialists giving such treatment, but he admitted that he had never seen such treatment given and knew nothing of it of his own knowledge. He testified that fractures can occur in shock treatments despite every precaution taken to prevent them. The plaintiff excepted to the admission of this evidence on the grounds that the witness was not qualified as an expert on the subject of shock treatment.

The trial court ruled that there was no evidence from which a jury would be warranted in finding that the defendant had been negligent and directed a verdict for the defendant. The plaintiff excepted to this ruling, and carried both questions to the Supreme Court of Tennessee.

The plaintiff took the position that since all the equipment and instrumentalities used to administer the treatment were within the exclusive control of the defendant, it was fair to infer that his injury was the result of negligence, thus attempting to invoke the doctrine of *res ipsa loquitur*. The Court, however, decided that this doctrine is applicable only when the injury is not ordinarily explainable except by negligence—for example, when a plaintiff's eye was injured while he was unconscious during an appendectomy, or when a piece of the plaintiff's tongue was cut off in an operation for adenoids. Under such circumstances a layman could infer negligence without any explanation from an expert, but the court was of the opinion that a layman could

not determine, without the help of an expert, whether or not, without negligence, a fracture could result from shock treatment. The court also gave weight to the fact that in this case the uncontradicted evidence of the expert was that such an injury could occur without negligence. (A somewhat different view of the doctrine of *res ipsa loquitur* and of the effect to be given to the fact that a patient was unconscious at the time he was injured prevailed in another case*).

The Supreme Court decided that the witness had sufficient knowledge of medicine and medical literature to entitle him to rely on a textbook acquaintance with the subject matter of his testimony. He was qualified as an expert because he had sufficient knowledge of the subject matter, and the source of his knowledge therefore affected only the weight to be attributed to his testimony and not his qualifications to testify. (*Quinley v Cocke*, 192 SW [2d] 992, March 2, 1946, Supreme Court of Tennessee.)

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

DISTRIBUTION OF ANTIMENINGOCOCCUS SERUM DISCONTINUED

Since the therapeutic value of sulfanilamide against meningococcal infection was first reported nine years ago,¹ it has been shown in many thousand cases that sulfonamides are the therapeutic agent of choice. As pointed out a few years ago in the *Journal*,² the mortality rates in groups of sulfonamide-treated cases frequently ran below 5 and rarely rose above 10 per cent—a result far superior to any that was ever obtained with serum therapy. Because of the remarkable efficacy of sulfonamide therapy in meningococcal meningitis, the Council on Pharmacy and Chemistry voted, in 1944, to omit antimeningococcus serum and meningococcus antitoxin from *New and Nonofficial Remedies*.³ Later in the year the following editorial comment⁴ was made:

Antimeningococcus serums are still used by some medical officers and civilian physicians, perhaps because they prefer to cling to tradition or because they assume that serum therapy is an essential part of "doing everything possible." There seems to be little if any reason for believing that this supplementary form of therapy is of additional benefit. Indeed there is increasing evidence that antimeningococcus serum, particularly when given by the intrathecal route, may actually do more harm than good in most drug-treated cases.

The demand for antimeningococcus serum in Massachusetts has practically ceased in the last two years, particularly since it has been shown that penicillin is a useful supplementary remedy in patients who are unable to tolerate sulfonamides or in whom the infective strain of meningococcus is

ACUTE MYOCARDIAL INFARCTION

A Study of 100 Consecutive Cases

WILLIAM N. CHAMBERS, M.D.*

HANOVER, NEW HAMPSHIRE

THIS study consists of detailed clinical observations on 100 consecutive cases of acute myocardial infarction at St. Luke's Hospital, New York City. Eighty-five of these patients were observed from one to ten years prior to the initial attack, for an average of four years, either on the wards or as outpatients. Follow-up studies of from one to four years were made on 64 of the 66 survivors.

The criteria used for making the diagnosis were those enumerated by Shillito et al.¹ fever, tachycardia, leukocytosis, elevated sedimentation rate and electrocardiographic and blood-pressure changes.

So far as could be determined, the observers were dealing with the initial attack in each case. With the present study in view each patient was carefully observed, and detailed clinical and laboratory evaluations were made. Serial electrocardiograms were taken until the infarct was considered healed. Follow-up study consisted of a brief history, physical examination, blood pressure readings and electrocardiograms.

Thirty-four per cent of the patients died of the initial attack. The average length of life after admission was seven days, the longest thirty days, and the shortest seven hours.

There is considerable variation in the literature regarding the percentage of initially fatal cases, ranging from 20 to 47 per cent.²⁻⁴ By the end of the first year 42 per cent of the patients in this series had died, 8 per cent from recurrent attacks.

INCIDENCE

Occupation

No correlation was found between the type of occupation or environment and the incidence of acute myocardial infarction. Rathe⁴ found that

persons living in rural areas were affected as often as those in urban areas.

Age

The average age of patients in the complete series was fifty-nine years. The oldest in the series was ninety and the youngest thirty-five years. The average age was sixty and a half years for patients who died during the initial attack, fifty-nine for those who died of a recurrence within a year of the initial attack and fifty-seven and a half for those who survived one year or more without recurrence. Patients in the initially fatal group were on the average three years older than those who survived more than a year, and one and a half years older than those who succumbed to a recurrence within a year of the initial attack.

The effect of age on immediate mortality has been pointed out by many observers, including Woods,² Levine,³ Rathe,⁴ Cooksey⁵ and Baer et al.⁶ In Bland and White's⁷ ten-year follow-up the average age was sixty-one years for patients who died of the initial attack, fifty-seven (at the time of the initial attack) for those who died within ten years and fifty-one for those who survived ten years.

Sex

In this series there were 72 men and 28 women—a ratio of approximately 3 to 1, the usually accepted figure, although Willius⁸ found a ratio of 7 to 1. Twenty men and 14 women died of the initial attack, the relatively higher mortality for the latter (50 per cent) than for the former (27 per cent) may be explained by the fact that the initial attack usually occurs later in women than in men. The average age at onset of the initial attack was sixty-three years for women and fifty-seven and three quarters for men, a difference of over five years. In cases in which the initial attack was fatal the average was sixty-five and a half years for women and fifty-eight

*Assistant in medicine, Hitchcock Clinic and Mary Hitchcock Memorial Hospital, teaching fellow, Dartmouth Medical School; formerly resident in medicine, St. Luke's Hospital, New York City.

tissues, organismal differentials in the maintenance of harmony of the organism as a whole, and in the interaction of the organs and tissues within the organism, immune processes in their bearing on the interpretation of organismal differentials, relation between the evolution of species and organismal differentials, and significance of individuality differentials in the psychosocial field—in which the concept of individuality had its origin.

There is a useful bibliography, followed by an author and subject index. This book, when read with considerable thought, will yield great profit.

The Embryology of Behavior. The beginnings of the human mind. By Arnold Gesell, M.D., Ph.D., Sc.D. In collaboration with Catherine S. Amatruda, M.D. 8°, cloth, 289 pp., with 78 illustrations, 44 plates and frontispiece. New York: Harper and Brothers, 1945. \$5.00.

This book should prove to be of immense practical value to all students of human behavior. The authors develop their theme in true scientific spirit. They state "[We attempt] to indicate how an organic complexus of behavior is built up concomitantly with the bodily development of embryo, fetus and neonate. Adopting a thoroughgoing monistic approach, we are under no necessity of defining a casual interaction between body and mind. We simply assume that as the soma takes shape, the psyche likewise takes shape. We are dealing with a single developmental morphology."

The first chapter is devoted to an instructive brief historical survey of primitive, descriptive and experimental embryology. The subsequent chapters, which are written in a clear style and are fortified by sketches and drawings, concern birth and age, zygote and embryo, genesis of behavior, the archaic motor system, the growth of fetal behavior, breathing behavior, muscle tonus, electrotonic integration, the fetal infant, the circumnate infant, the diurnal cycle of sleep and wakefulness, species and individual, the dynamic morphology of behavior and the hierarchical continuum. A striking feature of the book is a photographic delineation of behavior patterns and growth sequences. The appendix gives an example of the investigation in outline with specimen protocols.

There is a working list of selective references for each chapter, as well as a useful index. When one considers the recent effect of experimental embryology on the understanding of the constitution and the emphasis on psychosomatic medicine, one realizes that this volume is a basic contribution in this direction. It should be on the shelves of every library.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Bone-Grafting in the Treatment of Fractures. By J. R. Armstrong, M.D., M.Ch., F.R.C.S., A/W/Comm. R.A.F.M.S., and surgeon-in-charge of an R.A.F. orthopedic and fracture center, registrar to the Orthopaedic Department and to the Fracture Clinic, Charing Cross Hospital, London, and registrar to the Metropolitan Hospital, London. With a foreword by R. Watson-Jones, B.Sc., M.Ch.Orth., F.R.C.S., civilian consultant in orthopedic surgery of the Royal Air Force. 8°, cloth, 175 pp., with 204 illustrations. Baltimore: Williams and Wilkins Company, 1945. \$7.00.

In this monograph the author has attempted to bring together in one volume material relating to the special subject of bone grafting in the treatment of fractures. The text is well illustrated, and there is an adequate index.

An Index of Differential Diagnosis of Main Symptoms. By various writers. Edited by Herbert French, C.V.O., C.B.E., M.A., M.D. (Oxon.), F.R.C.P., consulting physician, Guy's Hospital, assisted by Arthur H. Douthwaite, M.D., F.R.C.P., physician, Guy's Hospital. Sixth edition. 4°, cloth, 1128 pp., with 789 illustrations. Baltimore: Williams and Wilkins Company, 1945. \$17.00.

This standard reference work, first published in 1912, has been fully revised, and many new laboratory tests and diagnostic methods have been included in this sixth edition. A comprehensive, inclusive index of 214 pages is appended to the text, making it possible to find in this condensed volume any subject mentioned therein. The work should be in the libraries of all general practitioners as a reference source. It is printed with a good type on filled paper, which makes it rather heavy to handle.

NOTICES

ANNOUNCEMENTS

Dr. J. Penteado Bill announces the removal of his office to the Professional Building, 270 Commonwealth Avenue, Boston.

Dr. Frank S. Broggi, having returned from military service, announces the opening of his office in Portland, Maine, for the practice of neurology and psychiatry.

Dr. Thomas G. Connelly announces the removal of offices from 676 Adams Street, Dorchester, and 270 Commonwealth Avenue, Boston, to 375 Commonwealth Avenue, Boston, for the practice of internal medicine.

Dr. Albert Y. Kevorkian announces the reopening of his office for the practice of gynecology, female urology and obstetrics at 422 Beacon Street, Boston.

Dr. Charles Gale Shedd has returned from military service and is resuming the practice of surgery at 422 Beacon Street, Boston.

Dr. L. Robert Weiss announces the removal of his office from 483 Beacon Street to 68 Bay State Road, Boston.

SUFFOLK CENSORS' MEETING

The Censors of the Suffolk District Medical Society will meet for the examination of candidates at the Boston Medical Library, 8 Fenway, on Thursday, December 5, 1946, at 4:00 p.m.

ASSOCIATION OF MILITARY SURGEONS

The convention of the Association of Military Surgeons of the United States will be held October 9 to 11, inclusive, in Detroit. Among the highlights of the meeting will be addresses by Colonel Ervin Abel, president of the association, by the Surgeons General of the United States Army, Navy and Public Health Service and by Major General Paul R. Hawley, of the Veterans Administration.

Any past or present medical, dental or veterinary officer of the United States Army, Navy, Public Health Service or Veterans Administration is eligible for membership in the association on application to the secretary, Colonel James M. Phalen, United States Army (retired), Army Medical Museum, Washington 25, D.C.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, SEPTEMBER 12

FRIDAY, SEPTEMBER 13

*10:00 a.m.-12:00 p.m. Medical Staff Rounds. Peter Bent Brigham Hospital.

12:00 p.m.-1:00 p.m. Clinicopathological Conference (Boston Hospital). Joseph H. Pratt. Diagnostic Hospital.

TUESDAY, SEPTEMBER 17

*12:15-1:15 p.m. Clinicoradiological Conference. Peter Bent Brigham Hospital.

(Voices continued on page xiv)

15 severe congestive failure. Thirteen patients were in shock. Friction rubs were heard in 6 cases. Three patients had ascites.

In the initially fatal series, rales and poor heart sounds were almost constant findings. Cyanosis occurred in over 66 per cent. More than 50 per cent of all patients in this series had some disturbance of rhythm, as well as extrasystoles and gallop. Of the 6 cases with auricular fibrillation, 4 were fatal. Edema was found in 50 per cent, and an enlarged liver in 33 per cent of fatal cases. Severe congestive failure, which appeared in 33 per cent of fatal cases, was infrequent in patients who survived and in those in shock. Four of the 6 cases with friction rubs were fatal. All patients with ascites died of the first attack of infarction.

X-ray study revealed cardiac enlargement in 76 per cent of the series. Master et al.^{9, 10} point out the importance of this factor in prognosis, a high percentage of patients with cardiac decompensation having enlarged hearts, the principal cause of death in coronary occlusion. They state that the favorable prognosis in young persons may well depend on the low incidence of cardiac enlargement. White and Bland¹¹ showed that there is a direct correlation between cardiac enlargement and mortality.

Although extrasystoles and gallop rhythm in themselves had no great effect on prognosis their persistence increased the gravity of the prognosis.¹²

There seemed to be a slight difference in the findings on admission between patients who died within a year and those who lived one year or more, disturbances in rhythm and signs of cardiac decompensation appearing more frequently in the former.

Pulse and Temperature

On admission the average pulse in the fatal cases was 115, rapid pulse usually persisted until death. The average rectal temperature for this group was 101.7°F, and the temperature remained elevated until death. In only 1 fatal case was there no evidence of tachycardia, and fever was present in all fatal cases.

The pulse in the surviving patients averaged 100 and remained rapid for an average of eight days, the temperature, which was slightly over 100°F on admission, usually fell to normal on the ninth or tenth day — one or two days after the pulse returned to normal.

Blood Pressure

Hypertension occurred in 74 per cent of the entire series, a rate definitely greater than that expected for the general population in this age group. The incidence was roughly the same in fatal (71 per cent) and nonfatal (77 per cent) cases. Hypertension at the onset of the attack was a frequent finding, being present in 53 per cent of the series, and was noted oftener in the fatal (68 per cent) than

in the nonfatal cases. Hypotension at the onset of the attack was a comparatively infrequent finding, occurring in 18 per cent of the cases.

A fall in blood pressure usually occurred following the attack, but the blood pressure often remained within hypertensive limits. The fall was usually immediate, but was sometimes delayed as long as seven days after the onset of the attack. An early return of blood pressure to normal or hypertensive levels was a good prognostic sign. The blood pressure usually did not return to its former levels in the fatal group. The number of survivors in whom the original hypertension recurred increased with time, 58 per cent had regained their hypertension by the second year. After recovery from the initial coronary occlusion the level of the blood pressure had no effect on the frequency of recurrence or on the ultimate prognosis.

LABORATORY FINDINGS

White-Cell Counts

The average white-cell count in the fatal cases was 20,000, reaching a peak by the second day. It invariably remained elevated until death. In the patients who survived, it averaged 13,000, the peak being reached on the first day, and the elevation being maintained for about ten days. The white-cell count was above 15,000 in 40 cases. Of the patients with counts between 15,000 and 20,000, 12 died and 12 survived. Of those with counts of 20,000 to 25,000, 5 died and 4 survived. Death occurred in all patients with counts over 25,000. The highest white-cell count was 39,000.

Sedimentation Rates

The erythrocyte sedimentation rate, which was elevated in 90 per cent of the nonfatal and in all the fatal cases, was in general no higher in the latter than in the former. Of the 38 patients whose rates exceeded 50 mm per hour, 24 survived and 14 died. There were 5 cases with rates over 100 mm per hour, only 1 of which was fatal. The highest rate of 128 mm occurred in a patient who survived.

Electrocardiograms

Tracings were taken on admission and subsequently on alternate days until stabilization, which usually occurred between the second and the third week. After discharge tracings were usually taken at intervals of three to six months.

Acute changes were found in all cases, 52 showing the anterior-apex type (Q₁ T₁), 40 the posterior-base type (Q₂ T₂) and 8 a combination of both types. The mortality was higher in the anterior-apex type (24 cases, or 47 per cent) than in the posterior-base type (15 cases, or 38 per cent). In patients with a combination of both types, the mortality was 100 per cent. Vander Veer and Brown¹³ found a nearly equal occurrence of anterior and posterior infarction patterns, but a significant percentage of the fatal

for men. For women the immediate mortality was greater and increased with advancing years.

HISTORY

A past history of symptoms referable to the cardiovascular system was found in 84 per cent of cases, the average duration of the symptoms being four years. Dyspnea was the most frequent symptom, being present in 44 per cent of cases. Anginal pain was present in 40 per cent, and symptoms of cardiac decompensation of varying degrees in 12 per cent. Most of these cases had been observed at this hospital prior to the initial attack in decompensation. Other prominent symptoms were easy fatigability and palpitation, which are usually reported.⁴ Hypertension was known to have existed in 74 per cent of cases.

Diseases appearing before the myocardial infarction were diabetes (13 per cent), syphilis (6 per cent), cerebral hemorrhage (5 per cent), and cancer (4 per cent). There were 3 cases of polycythemia vera, 2 of myxedema, 2 of glomerulonephritis, 2 of duodenal ulcer and 1 each of pernicious anemia and sprue. The presence of these diseases was demonstrated either in this hospital or by records from other hospitals. Three cases of cholecystitis were proved at operation, but 9 patients gave complaints suggestive of this condition. No patient on whom autopsy was performed showed evidence of acute or chronic cholecystitis. Some type of major surgical operation had been performed prior to the attack in 5 per cent of cases, but in no case did the onset of acute myocardial infarction appear to bear any relation to such procedures.

SYMPTOMS

Chief Complaint

The most prominent chief complaint was pain, which occurred in some form in 79 per cent of cases, 56 per cent of patients gave substernal pain as the chief complaint, 12 per cent complained of substernal pain and dyspnea, and 8 per cent had epigastric pain. There were 2 cases of right-upper-quadrant pain. Dyspnea was the second most prominent chief complaint, occurring in 26 cases — alone in 7, with weakness in 4, and with orthopnea in 3. Other chief complaints were syncope (3 cases), overwhelming fatigue and weakness (2 cases) and nausea and vomiting (1 case). It is of interest that pain was not even mentioned as a chief complaint in 21 per cent of cases. Substernal pain was the chief complaint in 80 per cent of patients who survived and in only 50 per cent of fatal cases. Of the 8 cases with epigastric pain, 5 were fatal. Severe dyspnea and orthopnea occurred more frequently in the fatal than in the nonfatal cases.

Nature of Pain

Investigation of the nature of pain revealed the following types of substernal pain: constricting,

of mild to moderate severity, 52 per cent, severe, crushing, 11 per cent, boring, 3 per cent, and choking, 3 per cent. Constricting pain occurred with equal frequency in the fatal and nonfatal cases. No correlation could be made between the intensity of pain and prognosis — of the 11 cases with complaint of severe to excruciating precordial pain, none was fatal. On the other hand, 21 per cent of the entire series of patients had no pain, of whom approximately 50 per cent died of the initial attack.

Epigastric pain was described in 8 cases, localization of pain in the epigastrium is apparently associated with a grave prognosis, for 5 of the 8 cases with this complaint were fatal.

Radiation of Pain

In this series radiation of pain occurred three times more frequently than nonradiation. The most frequent type was down the left arm. Other types were down the right arm, down both arms, up to the neck and into the jaw. When the pain occurred in the epigastrium or right upper quadrant, it did not radiate.

An attempt to correlate the radiation and death showed that radiation occurred in 83 per cent of nonfatal and 57 per cent of fatal cases, in the former, radiation was three times more frequent than nonradiation. Radiation to unusual areas occurred oftener in the nonfatal than in the fatal cases.

Duration of Pain

The time that elapsed between onset of pain and hospitalization varied considerably: seven and a half days for patients who had no pain, five and two thirds days for those who had intermittent, and eighteen hours for those with constant pain. Patients with pain were hospitalized earlier than those without pain, and, in general, patients who survived were hospitalized earlier than those who died.

Other Symptoms

Although pain was the outstanding chief complaint, other symptoms were prominent. Eighty-six per cent of patients had dyspnea of varying degrees, 50 per cent had weakness, and over 33 per cent had sweating. Nocturnal dyspnea, orthopnea, ankle edema, nausea and vomiting, which were present either singly or together in approximately 25 per cent of cases, appeared to have more effect than pain on the immediate prognosis, over 50 per cent of patients with these symptoms dying of the initial attack of infarction.

PHYSICAL FINDINGS

Physical examination on admission disclosed poor heart sounds and congestive rales in approximately 75 per cent and cyanosis in slightly less than 50 per cent of cases. Edema of varying degrees and disturbances of heart rhythm were noted in 33.3 per cent. Eighteen patients had enlarged livers, and

rences within this period were older (fifty-nine years) than those who had no recurrences (fifty-seven years). Men appeared more susceptible to fatal recurrence than women. The number of recurrences varied between one and three, the majority having only one in the period of observation.

The symptoms of cardiac decompensation were outstanding in the cases of fatal recurrence. Eighty-seven per cent were either on digitalis or had some symptoms of cardiac decompensation. Angina was present in only 50 per cent of this group.

In the cases of nonfatal recurrence angina was the outstanding symptom, being present in 88 per cent. Forty-four per cent of these patients either were on digitalis or had some symptom of cardiac insufficiency. Only 16 per cent of patients without recurrence either were on digitalis or had some symptom of cardiac insufficiency. Angina was present in approximately 50 per cent of these cases. Other complaints were infrequent, 22 per cent of these patients having no symptoms.

It is striking to note that the symptoms of cardiac insufficiency were most frequent among the fatally recurrent cases (75 per cent), much less frequent in patients who had nonfatal recurrences (33 per cent) and almost negligible in those who had no recurrence (8 per cent). Some degree of dyspnea was a fairly constant complaint in all three categories. Angina was more frequent in the cases of nonfatal recurrence than in either those of fatal recurrence or those of nonrecurrence.

In more than 50 per cent of Rathe's⁴ late fatal cases the patient had congestive heart failure, of the survivors only 20 per cent had this condition. In Bland and White's⁷ ten-year follow-up study, of the 30 per cent who survived 33.3 per cent had complete recovery, 33.3 per cent had angina, and 33.3 per cent had dyspnea.

No correlation could be made between the severity of the symptoms in the initial attack and the number of recurrent attacks, except for the cases of cardiac decompensation. The severity of the symptoms did not increase with the recurrences, whereas the incidence of decompensation did increase, and the prognosis was worse for those who had this condition. Decompensation, which was often not present during the first attack, usually appeared during the second.

Over 50 per cent of the patients who survived a year, with or without recurrence, were working, either full or part time. This percentage is lower than that given by Cooksey,⁵ who found that more than 75 per cent of the survivors returned to a useful occupation. Master et al.,¹⁷ in a series of 202 cases, reported that 50 per cent of the survivors were able to return to work.

AUTOPSY FINDINGS

The results of autopsy were reported in 18 cases, 15 in the initially fatal and 3 in the recurrent group.

In all cases there was evidence of acute myocardial infarction, with the exception of 1 case in which a healed infarction was found. Sixteen cases showed definite evidence of coronary occlusion. In only 1 case was there evidence of occlusion of both arteries. The left coronary artery was involved in 62 and the right in 38 per cent.

In Baer and Frankel's¹⁵ series 70 per cent showed anterior, 23 per cent posterior, and 7 per cent antero-posterior occlusion.

Mural thrombus, ruptured posterior wall of right ventricle, aneurysm of left ventricle and interventricular septum, pericarditis and pulmonary embolism were found in 1 case each. In no case did autopsy show the gall bladder to be involved, although 3 patients had complained of gall-bladder symptoms during life.

SUMMARY AND CONCLUSIONS

Clinical observations in 100 cases of acute myocardial infarction are presented.

The older the patient at the time of the initial attack, the more serious the prognosis. The incidence was higher among men than among women, but mortality was higher among women, whose attacks tended to occur later in life.

In patients who gave a past history of cardiac decompensation the mortality was higher. The long-standing presence of angina or dyspnea had no particular influence on the prognosis.

Although pain was an outstanding chief complaint, it was not present in 21 per cent of the cases. In the fatal cases only 25 per cent of patients had severe precordial pain. Excruciating precordial pain, if not intractable, did not carry a poor prognosis, intractable precordial pain and epigastric pain occurred often in the fatal cases. Radiation of pain had no relation to mortality.

The symptoms of excessive dyspnea, orthopnea, nausea, vomiting, excessive fatigue or weakness were found in over half the initially fatal cases. Such symptoms appeared to be more significant than pain in the immediate prognosis.

The physical findings of edema, enlarged liver, ascites and disturbances of rhythm carried a poor prognosis. Fever and tachycardia were always present in the initially fatal cases.

The incidence of hypertension was greater in patients with coronary occlusions (74 per cent) than in the general population. There was no correlation, however, between antecedent hypertension and mortality rate.

The sedimentation rate, which was of help in establishing the diagnosis, was elevated in 90 per cent of cases. The height of the sedimentation rate, however, bore no relation to the prognosis. The white-cell count, which was of help in both diagnosis and prognosis, was elevated in 90 per cent of the initially fatal and in 70 per cent of the non-fatal cases. With counts between 20,000 and 25,000

cases were of the anterior variety Levine and Rosenbaum¹⁴ noted that anterior infarction was more frequent in the initial attack than later In Baer and Frankel's cases¹⁵ 52 per cent were of the anterior and 34 per cent of the posterior type Rathe⁴ observed a definite predominance of anterior and indeterminate electrocardiographic patterns in early fatal cases Willius⁸ and Master et al¹⁶ attached little prognostic significance to the localization of the infarct

Persistent sinus tachycardia, which occurred in 16 cases, was seen twice as often in the fatal (11 cases) as in the nonfatal (5 cases) Nodal tachycardia appeared in 2 cases, both fatal Auricular extrasystoles were present in 6 fatal and 7 nonfatal cases Ventricular extrasystoles appeared in 15 nonfatal and 9 fatal cases Auricular flutter was noted in 3 cases, all nonfatal Auricular fibrillation appeared in 7 fatal and 3 nonfatal cases Auriculo-ventricular block was found in 2 fatal and 4 nonfatal cases Left bundle-branch block was present in 15 cases, 6 nonfatal and 9 fatal, 5 cases showed incomplete and 10 complete block Right bundle-branch block and unclassified bundle-branch block occurred in 1 case each The mortality was significantly higher in patients showing complete than in those showing incomplete block

At the end of a month after the initial attack all electrocardiograms that had shown acute changes continued to show residua, this was also true of the three-month follow-up By the sixth month 9, at the end of the first year 15, at eighteen months 21, and at the end of two years 38 per cent of the electrocardiograms had reverted to normal

In the series of Master et al¹⁷ the electrocardiogram was normal in 21 per cent of cases within a year of the attack The absence of typical electrocardiographic changes in the follow-up period is well discussed by Sussman and Dack¹⁸ and by Parkinson and Bedford¹⁹

In the recurrent cases, both fatal and nonfatal, electrocardiographic residua persisted in all but 1 There was no predominance of anterior over posterior type or evidence of the type of occlusion to be expected following the initial attack Bundle-branch block was present in 4 of the 8 patients who developed fatal recurrences within a year No other constant finding was present The prognosis was found to be better if the changes were slight Recurrence was rare in patients with normal electrocardiograms

CLINICAL COURSE

Congestive failure was the most frequent condition complicating the hospital course Thirty-three per cent of the patients either had such failure on admission or developed it while hospitalized Fifteen per cent were admitted with failure already present, and 18 per cent developed it after admission

In the fatal cases 10 patients (30 per cent) had cardiac failure on admission, and 12 (35 per cent) developed failure during the hospital course—a total of 22 cases, or 65 per cent Woods and Barnes,⁷ Levine,³ Rathe,⁴ and Falk²⁰ stress the frequency of congestive failure in fatal cases In the nonfatal cases, 16 patients (25 per cent) either had decompensation on admission or developed it subsequently In Rathe's⁴ series decompensation occurred in 20.2 per cent

Seventy-nine per cent of all patients had pain on admission, but intractable pain persisted in only 16 per cent Such pain occurred in over 25 per cent of fatal and in only 10 per cent of nonfatal cases Although no reference was found in the literature to the relation of persistence of pain to prognosis, the incidence in this series is significant.

Of the 6 patients admitted with auricular fibrillation, 4 died and 2 survived This condition developed during the hospital course in 4 other cases, 2 of which were fatal Fibrillation persisted until death in all fatal cases but stopped either spontaneously or following medication in all surviving patients Askey and Neurath²¹ pointed out that the prognosis is poor in patients with persistent fibrillation, they found this condition in 1 in every 12 cases as a complication of acute myocardial infarction Fibrillation was present at some time in 10 per cent of the present series

Pericarditis, as manifested by a friction rub with or without pain, occurred in 10 per cent of the cases, 7 of which were fatal Rathe⁴ found pericarditis in 10 per cent of his cases Pericardial friction rubs were reported by Shillito et al¹ in 20 per cent of their cases, and by Blumer²² in 21 per cent

Bronchopneumonia occurred in 3 fatal and 4 nonfatal cases Coma occurred in 6, all of which were early fatal cases Pulmonary embolism occurred in 5 per cent, none of them fatal In Falk's²⁰ series massive pulmonary embolism was given as one of the chief causes of death in coronary occlusion A review of the autopsies in the present series, however, revealed only 1 case of pulmonary embolism Cerebral hemorrhage occurred in 1 fatal and 1 nonfatal case

In the fatal cases the average duration of life was eleven days after the onset of acute symptoms and seven days after hospitalization, the survivors were usually admitted earlier—on the average, three days after onset of the symptoms Hospitalization was generally for six or seven weeks

FOLLOW-UP STUDIES

Of the original 100 patients, 66 survived the initial attack and 58 were alive at the end of a year Seventeen patients had recurrences within a year, 8 of which were fatal Forty-nine patients had no recurrences within this period Patients who died of recurrences within a year were older than those who survived, and those who had nonfatal recur-

rences within this period were older (fifty-nine years) than those who had no recurrences (fifty-seven years). Men appeared more susceptible to fatal recurrence than women. The number of recurrences varied between one and three, the majority having only one in the period of observation.

The symptoms of cardiac decompensation were outstanding in the cases of fatal recurrence. Eighty-seven per cent were either on digitalis or had some symptoms of cardiac decompensation. Angina was present in only 50 per cent of this group.

In the cases of nonfatal recurrence angina was the outstanding symptom, being present in 88 per cent. Forty-four per cent of these patients either were on digitalis or had some symptom of cardiac insufficiency. Only 16 per cent of patients without recurrence either were on digitalis or had some symptom of cardiac insufficiency. Angina was present in approximately 50 per cent of these cases. Other complaints were infrequent, 22 per cent of these patients having no symptoms.

It is striking to note that the symptoms of cardiac insufficiency were most frequent among the fatally recurrent cases (75 per cent), much less frequent in patients who had nonfatal recurrences (33 per cent) and almost negligible in those who had no recurrence (8 per cent). Some degree of dyspnea was a fairly constant complaint in all three categories. Angina was more frequent in the cases of nonfatal recurrence than in either those of fatal recurrence or those of nonrecurrence.

In more than 50 per cent of Rathe's⁴ late fatal cases the patient had congestive heart failure, of the survivors only 20 per cent had this condition. In Bland and White's⁷ ten-year follow-up study, of the 30 per cent who survived 33.3 per cent had complete recovery, 33.3 per cent had angina, and 33.3 per cent had dyspnea.

No correlation could be made between the severity of the symptoms in the initial attack and the number of recurrent attacks, except for the cases of cardiac decompensation. The severity of the symptoms did not increase with the recurrences, whereas the incidence of decompensation did increase, and the prognosis was worse for those who had this condition. Decompensation, which was often not present during the first attack, usually appeared during the second.

Over 50 per cent of the patients who survived a year, with or without recurrence, were working, either full or part time. This percentage is lower than that given by Cooksey,⁵ who found that more than 75 per cent of the survivors returned to a useful occupation. Master et al,¹⁷ in a series of 202 cases, reported that 50 per cent of the survivors were able to return to work.

AUTOPSY FINDINGS

The results of autopsy were reported in 18 cases, 15 in the initially fatal and 3 in the recurrent group.

In all cases there was evidence of acute myocardial infarction, with the exception of 1 case in which a healed infarction was found. Sixteen cases showed definite evidence of coronary occlusion. In only 1 case was there evidence of occlusion of both arteries. The left coronary artery was involved in 62 and the right in 38 per cent.

In Baer and Frankel's¹⁵ series 70 per cent showed anterior, 23 per cent posterior, and 7 per cent antero-posterior occlusion.

Mural thrombus, ruptured posterior wall of right ventricle, aneurysm of left ventricle and interventricular septum, pericarditis and pulmonary embolism were found in 1 case each. In no case did autopsy show the gall bladder to be involved, although 3 patients had complained of gall-bladder symptoms during life.

SUMMARY AND CONCLUSIONS

Clinical observations in 100 cases of acute myocardial infarction are presented.

The older the patient at the time of the initial attack, the more serious the prognosis. The incidence was higher among men than among women, but mortality was higher among women, whose attacks tended to occur later in life.

In patients who gave a past history of cardiac decompensation the mortality was higher. The long-standing presence of angina or dyspnea had no particular influence on the prognosis.

Although pain was an outstanding chief complaint, it was not present in 21 per cent of the cases. In the fatal cases only 25 per cent of patients had severe precordial pain. Excruciating precordial pain, if not intractable, did not carry a poor prognosis, intractable precordial pain and epigastric pain occurred often in the fatal cases. Radiation of pain had no relation to mortality.

The symptoms of excessive dyspnea, orthopnea, nausea, vomiting, excessive fatigue or weakness were found in over half the initially fatal cases. Such symptoms appeared to be more significant than pain in the immediate prognosis.

The physical findings of edema, enlarged liver, ascites and disturbances of rhythm carried a poor prognosis. Fever and tachycardia were always present in the initially fatal cases.

The incidence of hypertension was greater in patients with coronary occlusions (74 per cent) than in the general population. There was no correlation, however, between antecedent hypertension and mortality rate.

The sedimentation rate, which was of help in establishing the diagnosis, was elevated in 90 per cent of cases. The height of the sedimentation rate, however, bore no relation to the prognosis. The white-cell count, which was of help in both diagnosis and prognosis, was elevated in 90 per cent of the initially fatal and in 70 per cent of the non-fatal cases. With counts between 20,000 and 25,000

cases were of the anterior variety. Levine and Rosenbaum¹⁴ noted that anterior infarction was more frequent in the initial attack than later. In Baer and Frankel's cases¹⁵ 52 per cent were of the anterior and 34 per cent of the posterior type. Rathe⁴ observed a definite predominance of anterior and indeterminate electrocardiographic patterns in early fatal cases. Willius⁸ and Master et al¹⁶ attached little prognostic significance to the localization of the infarct.

Persistent sinus tachycardia, which occurred in 16 cases, was seen twice as often in the fatal (11 cases) as in the nonfatal (5 cases). Nodal tachycardia appeared in 2 cases, both fatal. Auricular extrasystoles were present in 6 fatal and 7 nonfatal cases. Ventricular extrasystoles appeared in 15 nonfatal and 9 fatal cases. Auricular flutter was noted in 3 cases, all nonfatal. Auricular fibrillation appeared in 7 fatal and 3 nonfatal cases. Auriculo-ventricular block was found in 2 fatal and 4 nonfatal cases. Left bundle-branch block was present in 15 cases, 6 nonfatal and 9 fatal, 5 cases showed incomplete and 10 complete block. Right bundle-branch block and unclassified bundle-branch block occurred in 1 case each. The mortality was significantly higher in patients showing complete than in those showing incomplete block.

At the end of a month after the initial attack all electrocardiograms that had shown acute changes continued to show residua, this was also true of the three-month follow-up. By the sixth month 9, at the end of the first year 15, at eighteen months 21, and at the end of two years 38 per cent of the electrocardiograms had reverted to normal.

In the series of Master et al¹⁷ the electrocardiogram was normal in 21 per cent of cases within a year of the attack. The absence of typical electrocardiographic changes in the follow-up period is well discussed by Sussman and Dack¹⁸ and by Parkinson and Bedford.¹⁹

In the recurrent cases, both fatal and nonfatal, electrocardiographic residua persisted in all but 1. There was no predominance of anterior over posterior type or evidence of the type of occlusion to be expected following the initial attack. Bundle-branch block was present in 4 of the 8 patients who developed fatal recurrences within a year. No other constant finding was present. The prognosis was found to be better if the changes were slight. Recurrence was rare in patients with normal electrocardiograms.

CLINICAL COURSE

Congestive failure was the most frequent condition complicating the hospital course. Thirty-three per cent of the patients either had such failure on admission or developed it while hospitalized. Fifteen per cent were admitted with failure already present, and 18 per cent developed it after admission.

In the fatal cases 10 patients (30 per cent) had cardiac failure on admission, and 12 (35 per cent) developed failure during the hospital course—a total of 22 cases, or 65 per cent. Woods and Barnes,² Levine,³ Rathe,⁴ and Falk²⁰ stress the frequency of congestive failure in fatal cases. In the nonfatal cases, 16 patients (25 per cent) either had decompensation on admission or developed it subsequently. In Rathe's⁴ series decompensation occurred in 20 per cent.

Seventy-nine per cent of all patients had pain on admission, but intractable pain persisted in only 16 per cent. Such pain occurred in over 25 per cent of fatal and in only 10 per cent of nonfatal cases. Although no reference was found in the literature to the relation of persistence of pain to prognosis, the incidence in this series is significant.

Of the 6 patients admitted with auricular fibrillation, 4 died and 2 survived. This condition developed during the hospital course in 4 other cases, 2 of which were fatal. Fibrillation persisted until death in all fatal cases but stopped either spontaneously or following medication in all surviving patients. Askey and Neurath²¹ pointed out that the prognosis is poor in patients with persistent fibrillation, they found this condition in 1 in every 12 cases as a complication of acute myocardial infarction. Fibrillation was present at some time in 10 per cent of the present series.

Pericarditis, as manifested by a friction rub with or without pain, occurred in 10 per cent of the cases, 7 of which were fatal. Rathe⁴ found pericarditis in 10 per cent of his cases. Pericardial friction rubs were reported by Shillito et al¹ in 20 per cent of their cases, and by Blumer²² in 21 per cent.

Bronchopneumonia occurred in 3 fatal and 4 nonfatal cases. Coma occurred in 6, all of which were early fatal cases. Pulmonary embolism occurred in 5 per cent, none of them fatal. In Falk's²⁰ series massive pulmonary embolism was given as one of the chief causes of death in coronary occlusion. A review of the autopsies in the present series, however, revealed only 1 case of pulmonary embolism. Cerebral hemorrhage occurred in 1 fatal and 1 nonfatal case.

In the fatal cases the average duration of life was eleven days after the onset of acute symptoms and seven days after hospitalization, the survivors were usually admitted earlier—on the average, three days after onset of the symptoms. Hospitalization was generally for six or seven weeks.

FOLLOW-UP STUDIES

Of the original 100 patients, 66 survived the initial attack and 58 were alive at the end of a year. Seventeen patients had recurrences within a year, 8 of which were fatal. Forty-nine patients had no recurrences within this period. Patients who died of recurrences within a year were older than those who survived, and those who had nonfatal recur-

USE OF SULFADIAZINE IN PRESENCE OF HEMATURIA

MAJOR JOSEPH H NICHOLSON, M C , A U S

IT is the purpose of this paper to discuss the renal reactions that occur after administration of sulfadiazine and to determine whether the clinical criteria generally accepted as indications for discontinuance of the drug are justifiable

The principal toxic reaction to sulfadiazine is renal irritation. Plummer and Wheeler¹ reported that of 705 patients receiving 2 to 4 gm initially, followed by 1 gm every four hours for not less than two and not more than fourteen days, 8 per cent showed definite evidence of toxicity to sulfadiazine, and that 48 per cent had renal irritation. Thus, more than half the cases of toxicity to the drug were due to renal irritation. Of 244 patients given one or more intravenous injections of sodium sulfadiazine, 12.3 per cent had some form of reaction and renal reactions occurred in 7.4 per cent. Thus, with intravenous sodium sulfadiazine, the incidence of renal reaction was almost doubled. It was also shown that the incidence of toxicity was generally in direct proportion to the concentration of sulfadiazine in the blood.

Disturbance of renal function resulting from sulfonamides has been well classified by Murphy et al.² into two types, the first of which comprises mechanical complications produced by masses of crystals of the sulfonamide compounds in the kidney tubules, pelves and ureters. This type may be further subdivided into the extraneuphric, in which the concretions causing obstruction are within the pelves of the kidneys or in the ureters, and the intraneuphric, in which the concretions are in the kidney substance itself. The second category includes toxic intrarenal lesions without mechanical obstruction. Such lesions occur within the kidney and may be attributed to the toxic effect of the sulfonamide compound on the parenchymal tissues. This class may be divided into three groups representing different phases of the same reaction and not distinct divisions — simple tubular degeneration, necrotic tubular degeneration and glomerular changes. In some cases there is evidence of obstructive and toxic parenchymal changes in the same kidney.

This brings up the question of the clinical manifestations that are indications for the discontinuance of sulfadiazine. The urinary reactions to sulfadiazine are microscopic hematuria, gross hematuria, renal pain (usually pain similar to that in renal infarction and typical ureteral colic), oliguria and anuria. There is divided opinion regarding which of these conditions demand discontinuance of the

drug. The appearance of microscopic or macroscopic hematuria, renal colic or anuria has been held to be a definite indication for stoppage of the drug.^{3,4} On the other hand, microscopic hematuria⁵ and ureteral colic⁶ have not been considered definite contraindications to its continuation.

In an attempt to determine just what clinical criteria should be used in ascertaining whether the drug should be discontinued in the presence of renal complication resulting from sulfadiazine therapy, the renal reactions resulting from such therapy on the meningitis service of the Fort McClellan Regional General Hospital were reviewed.

The incidence of urinary complications is generally quite high in patients with meningococcal meningitis or meningococcemia, the reported percentages varying from 5 to about 26 in large groups of patients.⁵⁻⁸ This incidence would be lower if microscopic hematuria were not considered a complication. In smaller series no renal reactions were encountered.⁹

At this hospital all patients with meningococcal infections are given an initial oral dose of 4 gm of sulfadiazine, followed by 2 gm every four hours. Frequently, oral administration is not possible because of vomiting or because of the semistuporous and maniacal condition of the patient. In such cases, an initial intravenous dose of 5 gm of sodium sulfadiazine is given, followed by repeated intravenous injections in doses of 2.5 or 5.0 gm, the amount depending on the blood level, which is maintained at 10 to 15 mg per 100 cc. In some cases it was impossible to maintain an adequate blood level by oral administration, but with improvement in the patient's general condition adequate blood levels were easily maintained. When oral administration was not possible intravenous sodium sulfadiazine was given. As pointed out by other observers,¹⁰ marked and unpredictable variations in blood sulfadiazine concentration followed both intravenous injection and oral administration, although fluctuations were generally less marked with the latter route. This fact emphasizes what has often been stated, namely, that frequent determinations of the blood level are essential. During the first twenty-four hours, 10 to 20 gm of sodium sulfadiazine was frequently given intravenously, and as much as 50 gm within a period of three days.

Recently alkalies have been advocated as adjuvants to sulfadiazine. It has been shown that with an alkaline urine the solubility of both free and acetylated sulfadiazine crystals is markedly increased.¹⁰ The recommendation has been made that

the prognosis was grave, but with those above 25,000 the mortality was 100 per cent

Electrocardiographic evidence of involvement of the left coronary artery was more frequent (52 per cent) than that of the right coronary artery (40 per cent), and the mortality was higher in patients with the former. Persistent sinus tachycardia, auricular fibrillation and complete bundle-branch block carried a grave prognosis. Stabilization of the electrocardiogram following the acute changes occurred by the beginning of the third week. Persistence of residua in the follow-up electrocardiograms was more frequent in the recurrent than in the nonrecurrent cases. There was no recurrence in cases in which the electrocardiograms reverted to normal.

Cardiac decompensation developed during the hospital course in over half the fatal cases and in less than one fifth the nonfatal cases. Patients who developed the signs of pericarditis had a high mortality, those who were admitted in coma or who went into coma died.

The older the patient at the time of the initial attack, the greater the likelihood of recurrence. Men succumbed to recurrences oftener than women. Cardiac decompensation was more frequent in patients with either fatal (87 per cent) or nonfatal (47 per cent) recurrences.

Findings at autopsy confirmed the predominance of involvement of the left (62 per cent) over that of the right coronary artery (38 per cent) shown by electrocardiogram.

a solution has an alkalinizing effect in the body equivalent to an oral dosage of 15 gm of sodium bicarbonate, and 1000 to 1500 cc renders the urine alkaline in patients with acidosis from acute infections. Once the urine is alkaline a total daily dosage of 1100 cc of one-sixth molar sodium lactate solution, given in two twelve-hour injections, is sufficient to maintain alkalinity. It is reported that with this solution practically no renal irritations followed intravenous administration of sodium sulfadiazine.¹¹

In this series of patients adequate hydration and alkalinization of the urine was obtained by the administration of at least 3000 cc of fluids and by the use of alkalis. Twelve to 20 gm of sodium bicarbonate was given orally in repeated equal doses every four hours. In the majority of cases 15 gm, divided into 2 5-gm doses, was given every

four hours. In distilled water it was immediately followed by either Hartman's or Ringer's solution in doses of 1000 or 1500 cc. In some cases 5 per cent glucose in normal saline solution was given.

Group 2 included 18 cases with similar diagnoses in which one-sixth molar solution of sodium lactate was used instead of Hartman's solution. In these cases, the sodium sulfadiazine was dissolved in the lactate solution to make a 1 per cent solution and was given intravenously. Generally no more than 2000 cc of one-sixth molar solution of sodium lactate was given in a twenty-four-hour period.

In Group 1 there were renal reactions in 12 cases, 4 showing microscopic and 8 gross hematuria (Table 1). In Group 2 there were 2 cases of gross hematuria (Table 2).

A record of the fluid intake and output was not obtained in all cases. Charts had been kept at the

four hours. When patients were unable to take or retain anything by mouth, fluids were given intravenously. The alkalinity of the urine was generally maintained at pH 7.5 or higher, each specimen being tested with nitrazine paper to determine its reaction. When it was below pH 7.5, either Hartman's solution or one-sixth molar sodium lactate solution was given intravenously, or the amount of sodium bicarbonate was increased.

The laboratory findings in the cases in which renal reactions occurred during sulfadiazine therapy are presented in Tables 1 and 2. These cases were divided into groups.

Group 1 included the renal reactions occurring in a study of 50 cases of meningococcal meningitis and meningococcemia in which alkalinization was carried out by the use of sodium bicarbonate in the doses described above when oral medication was possible, and by the use of Hartman's solution when oral medication was impossible. When intravenous sodium sulfadiazine was given in a 5 per cent solu-

tion in distilled water it was immediately followed by either Hartman's or Ringer's solution in doses of 1000 or 1500 cc. In some cases 5 per cent glucose in normal saline solution was given.

Three of 4 cases with microscopic hematuria had a urinary alkalinity of pH 7.5, and in 6 of 10 cases with gross hematuria the reaction was pH 7.5.

In no case was the sulfadiazine stopped because of hematuria, either microscopic or macroscopic, and in all cases the urinary output was adequate. If the urine was not alkaline, attempts were made to render it so, either by an increase in the dose of sodium bicarbonate or by the administration of Hartman's or Ringer's solution. In cases in which one-sixth molar solution of sodium lactate was used the urinary reaction was always alkaline. When hematuria occurred in both groups an additional 1000 cc of Hartman's, Ringer's or one-sixth molar lactate solution was given intravenously.

15 gm of sodium bicarbonate, or various amounts of other sodium salts with equivalent available base excess, be given daily in divided doses of 2.5 gm

tract obstruction was encountered during treatment with sulfadiazine orally or with sodium sulfadiazine intravenously¹ More recently, one-sixth molar

THE USE OF ETHER IN THE NARCOANALYSIS OF PATIENTS
WITH WAR NEUROSES

HENRY H BREWSTER, M D *

PHILADELPHIA

THIS report deals with the technic and utility of ether in the treatment of war neuroses. Comparing ether to Pentothal, as used by Grinker and Spiegel,¹ Sargant and Shorvon² and Kelley³ found the former more effective for ventilating repressed emotions in acute war neuroses. That ether is useful in psychotherapy for other reasons is suggested by Sargant and Shorvon and also by Rogerson⁴ in his account of nitrous oxide narcoanalysis of civilian patients with acute and chronic anxiety. Between January and May, 1945, ether was used at the 5th General Hospital in France in the psychotherapy of 100 neuropsychiatric patients. To comprehend the particular usefulness of ether one must understand the local problem of psychotherapy that existed at the hospital. The patients treated were, in general, combat soldiers who had been evacuated from the front for psychiatric reasons and who had spent from two to six weeks in other hospitals en route. In some cases Pentothal had been used at the forward hospitals, in others, the patients had received sedation and rest. On arrival at the 5th General Hospital, the patient usually presented a combination of certain persistent symptoms, such as anxiety and tremulousness, sensitivity to noise, anorexia, recurrent terrifying dreams and insomnia, irritability and, often, a generalized headache. In a small number of cases aphonia, weakness of the legs and other grossly hysterical symptoms were present, without external evidence of anxiety. The selected patient received a two-week program of treatment. A medical examination was completed, and a brief psychiatric history was taken, with special attention to the circumstances immediately preceding the patient's psychiatric breakdown as well as to the content of his dreams, both of which supplied starting points for an ether interview. On the day after admission to the hospital,

the patient received an ether interview, which was followed by two days of light sedation† during the afternoon and night and insulin therapy‡ in the morning. During the next three days the patient received insulin in the morning and group psychotherapy and physical exercises in the afternoon. After this period of treatment, he was transferred to a reconditioning company separated from the other hospital patients and under the command of a nonmedical officer, where he lived the life of a garrison infantry company and was assigned to duties necessary to the running of a hospital and peculiar to his own ability. After ten such days in the reconditioning company the patient was interviewed and re-evaluated by the psychiatrist. The ether examinations were done in a semi-darkened room. The patient was told in the morning that he would be interviewed in the afternoon with the aid of some medicine that would make it easy for him to talk about his experiences. In preparation for ether he received no food for six hours and 0.6 mg of atropine sulfate subcutaneously half an hour before the interview. None of the major complications of ether administration occurred. It should be noted that patients as a rule did not receive sedation preceding the interview, in 5 patients who had received sodium amytal the day before the interview, only an ineffective emotional response could be obtained under ether. Ether was administered by the open-drop method by a trained anesthetist. The patient was prompted by the psychiatrist to relate in chronologic order the events leading up to his psychiatric difficulties. Within two to five minutes the patient reached a mental state in which he was reliving his painful battlefield experience and expressing the emotion

*Fellow in psychiatry, Psychiatric Institute, Pennsylvania Hospital. This work was carried out when the author was a major in the Medical Corps of the United States Army on active duty overseas.

†After lunch 0.4 gm sodium amytal was given by mouth, and after supper 0.6 to 0.8 gm.

‡About 50 units of regular insulin was injected subcutaneously at 10:00 a.m. producing mild symptoms of hypoglycemia which were relieved by a high-calorie lunch at 12:00 p.m. The insulin therapy generally increased the patient's appetite, caused him to gain weight and reduced to a minimum the hangover associated with the use of sodium amytal.

DISCUSSION

In these 14 cases of renal irritation occurring during sulfadiazine therapy for meningococcal infections, 4 patients had microscopic and 10 gross hematuria. In spite of the hematuria, continuation of sulfadiazine therapy had no untoward effects, and in all cases the urine returned to normal. Such continuation of the drug in the presence of hematuria, particularly gross hematuria, is in disagreement with generally accepted procedure and calls for evaluation. Many cases of renal reaction from sulfadiazine, some fatal and others requiring either drastic treatment, such as ureteral and pelvic lavage and nephrostomy, have been reported in the literature.¹²⁻²⁰

In all the cases reported in the literature the urinary output varied from definitely diminished to absent, and alkalinization of the urine was not attempted or was inadequate. Fox et al.²¹ have pointed out the value of alkali therapy in the prevention of renal reactions, as well as the fact that adequate doses of alkalis must be given and that the required quantity of alkalis must be governed primarily by the reaction of the urine.

In spite of alkalinization of the urine, however, renal reactions from sulfadiazine occurred in the cases discussed above. To afford a good method of comparison, there is available the incidence of renal reactions at this hospital prior to the use of alkalis as adjunctive therapy, as reported by Marangoni and D'Agati.⁶ In 46 cases of meningococcal infection in which both oral and intravenous sulfadiazine were given 26 per cent of patients showed toxic renal reactions. This was only a slightly higher incidence than that in cases in which oral sulfadiazine was used alone. But the dosage was larger than that ordinarily given, with blood sulfadiazine levels of 15 to 20 mg per 100 cc. In a similar group of patients with alkaline urine, as reported above, there were renal reactions in approximately 13 per cent. This is an appreciable lowering of rate but is not in accord with other observations that alkalinization of the urine will check renal reactions. In none of the cases discussed above was there definite evidence of diminished urinary excretion or of renal colic, although renal colic may have been present in some cases for a fair percentage of the patients were semistuporous and disoriented and were therefore not easily observed, conscious and rational patients, however, gave no complaint that might have been interpreted as renal colic.

The renal irritation resulting from the use of sulfonamides is described above. Plummer and Wheeler,¹ however, in autopsies on 6 patients with renal irritation during sulfadiazine therapy who died of other causes, found concretions of the drug in the renal pelvis and deposits of the drug within the renal parenchyma, with tubular degeneration and interstitial inflammatory reaction and occasional

secondary degeneration of the nephron, they believed that no permanent or serious impairment of renal function would have ensued in the patients examined.

The factors that might be expected to influence the occurrence of renal reactions from sulfadiazine are the total dosage of the drug and the route of administration, the fluid balance, the reaction of the urine and individual sensitivity to the drug.

Most renal reactions occurring during sulfadiazine therapy are due to mechanical complications resulting from crystallization in the substance and pelvis of the kidneys and in the ureters. Clinically, however, renal irritations due to mechanical complication and those caused by the toxic effect of the drug on the kidneys cannot always be differentiated. The presence of renal or ureteral colic and crystal linuria suggests mechanical complications, but such symptoms and findings may be absent and the only sign may be hematuria, oliguria or anuria, even though concretions of sulfadiazine crystals are responsible for the renal reactions.

The most significant finding in renal reactions from sulfadiazine is not the presence of hematuria, with or without crystallinuria, but urinary output and alkalinity. If the urine is kept alkaline and fluid balance maintained, sulfadiazine can be continued, as in all the cases discussed above, which cleared without any evidence of residual damage.

CONCLUSION

Hematuria, either microscopic or macroscopic, is not a contraindication to continued use of sulfadiazine provided there is no diminished urinary output and provided the urine is kept alkaline and the fluid balance is maintained.

sleepy or groggy and subsequently remember nothing of the interview. The clinical value of abreaction is lost if the patient has amnesia for the procedure,⁶ since the amnesia represents the same state of repressed emotions that existed preceding the interview. Finally, ether has a pharmacologic value: it is absorbed readily by the lungs, produces its clinical effect promptly, and is eliminated quickly and in large part by the lungs. Because of its rapid elimination it is possible to lighten the level of ether anesthesia speedily by controlling the quantity being given the patient; Pentothal does not have this advantage.

The ether interview provided a useful means of surveying the conflicts of a neurotic patient and selecting patients suitable for the two-week program of treatment, and was also useful in clarifying a diagnosis, as when a mute patient under ether appeared to suffer from a case of severe anxiety, hysteria or psychosis. Ether is contraindicated in severely agitated patients, however, in whom it may release a dangerous amount of anxiety.

Under the circumstances described above ether interviews were an adjunct in treatment of patients who had had little previous psychiatric difficulty but had developed moderate to severe anxiety during and after combat, and of those with hysteria. That ether was a significant factor in the therapeutic results obtained from the two-week treatment program outlined is suggested by the following statistics. Fifty neurotic patients received this two-week program of treatment except that the

ether interviews were omitted, only 2 of these patients were capable of resuming duty overseas. One hundred similar patients received the two-week program of treatment, including the ether interviews. Of these, 50 were satisfactorily performing noncombat duty overseas one and two months after discharge from the hospital.

SUMMARY

A technic of administering ether to the psychiatric patient is described.

Ether was found to have the following advantages: it produced an excessive emotional response and maintained a useful hypnotic state for abreaction.

An interview under ether was a quick and useful method of surveying the conflicts of neurotic patients coming to an Army general hospital from combat.

In the treatment of 100 such patients in France, selected for two weeks of psychotherapy, ether interviews were found to be a significant adjunct to treatment.

associated with it. It was necessary for two to four attendants to restrain the patient during the excitement that generally occurred while he was reliving a traumatic incident. As soon as he had made the mental transition to a hypnotic state, ether administration was stopped. The patient subsequently remained in this state as long as the psychiatrist chose to maintain it. This allowed the psychiatrist to probe a traumatic incident, to recover the facts of the amnesic period frequent in such cases and to investigate the past history and its associated conflicts—in short, to abreact the patient at will and to the extent indicated. Occasionally the patient suddenly came out of the hypnotic state, and ether was readministered. In an hour's interview, it was sometimes necessary to administer ether once, twice or three times. The psychiatrist brought the patient out of the hypnotic state by reviewing chronologically the events leading up to admission to the hospital. Since the patient was conscious throughout the ether interview, he did not usually forget the material discussed during the abreaction.

Sometimes a patient is unduly slow in making the transition to the hypnotic mental state. When a patient who has been asked to narrate the events leading up to his mental breakdown begins to grow anxious or restless, the psychiatrist should intensify verbal, auditory or visual suggestion. Suddenly the patient talks in the present rather than the past tense, regards the psychiatrist as some person in his past experience, and is fully hypnotized. When difficulty is encountered in hypnosis particular factors should be considered. One is that the patient may be breathing with shallow respiration, making use only of his upper chest and thus indefinitely postponing the effect of the ether. To remedy the situation the psychiatrist should hold his hands against the lower lateral thorax and instruct the patient to take deep breaths, the patient thereby increases the excursion of respiration and inhales a larger quantity of ether.

Another factor to remember is that, during the ether induction, the psychiatrist may be suggesting to the patient a series of events that the psychiatrist thought, on eliciting the medical history, had been traumatic, but that actually had little emotional impact for the patient. For example, in giving his medical history preceding the ether interview, a patient states that he grew anxious during combat, that one day a shell burst near him and that he remembered nothing until he awoke in a hospital. The psychiatrist suggests these events during ether induction but finds that the mention of shellfire provokes little emotional response and that the patient remains un hypnotized. In that event, the psychiatrist should allow the patient to be etherized just short of unconsciousness and should then investigate further the medical history. Eventually he will discover the circumstances that are really

charged with emotion for the patient—a shell burst near him on the battlefield, he saw his buddy torn to shreds, he burst into tears and grew confused, and finally he was carried on a litter to a hospital, where his mental state was found to be anxious, agitated and disoriented. These remarks are most applicable to a chronic neurotic patient for whom combat experience has precipitated symptoms but for whom the conflicts of civilian life are associated with a far greater emotional charge. During the ether interview, such patients may well, by a process of free association, change their train of thought from combat experience to the more significant episodes of earlier life.

It should be borne in mind that in any patient aspiration of stomach contents and apnea may occur during ether anesthesia, but the chance is slight if the patient has fasted for six hours and has been atropinized. It should not be attempted if the patient has a pulmonary infection. The factor of safety is further increased if the anesthetist is experienced and an oxygen tank and mask are available.⁵ The complications mentioned above can develop quickly and unexpectedly and must be handled expeditiously and correctly. In general, however, ether is a safe drug for use in psychotherapy. Since it is absorbed and eliminated rapidly by the lungs, the level of anesthesia can be maintained easily and lowered more rapidly than that of intravenous drugs like Pentothal. It has been thought that the emotional excitement of patients during an ether interview is the same as that often seen in the surgical operating room during ether anesthesia. As Searles⁵ points out, however, the latter excitement occurs during the primary stage of ether anesthesia—a state during which, by definition, the patient is unconscious. During the psychiatric interview under ether, on the other hand, the patient is always conscious. Therefore the psychiatric patient must be in a stage just short of the accepted primary stage of ether anesthesia. During this preprimary stage, Searles believes that auditory stimuli are greatly exaggerated. Hence, the auditory suggestions made by the psychiatrist must be aggravated to a frightening degree by the action of ether. This observation may explain why ether seems to precipitate a greater emotional response than Pentothal, which is a sedative as well as an anesthetic.

Under the qualifying circumstances described above, ether presented several striking attributes in the treatment of combat neuroses. The most prominent was that in most cases it precipitated quickly an intense emotional response, which is a prerequisite for successful abreaction.⁶ A second attribute was that the ether produced a useful mental state for abreaction: the patient was conscious and alert during and after the interview, retaining a memory of what had transpired. Patients who have received Pentothal often grow

sleepy or groggy and subsequently remember nothing of the interview. The clinical value of abreaction is lost if the patient has amnesia for the procedure,⁶ since the amnesia represents the same state of repressed emotions that existed preceding the interview. Finally, ether has a pharmacologic value: it is absorbed readily by the lungs, produces its clinical effect promptly, and is eliminated quickly and in large part by the lungs. Because of its rapid elimination it is possible to lighten the level of ether anesthesia speedily by controlling the quantity being given the patient; Pentothal does not have this advantage.

The ether interview provided a useful means of surveying the conflicts of a neurotic patient and selecting patients suitable for the two-week program of treatment, and was also useful in clarifying a diagnosis, as when a mute patient under ether appeared to suffer from a case of severe anxiety, hysteria or psychosis. Ether is contraindicated in severely agitated patients, however, in whom it may release a dangerous amount of anxiety.

Under the circumstances described above ether interviews were an adjunct in treatment of patients who had had little previous psychiatric difficulty but had developed moderate to severe anxiety during and after combat, and of those with hysteria. That ether was a significant factor in the therapeutic results obtained from the two-week treatment program outlined is suggested by the following statistics: Fifty neurotic patients received this two-week program of treatment except that the

ether interviews were omitted, only 2 of these patients were capable of resuming duty overseas. One hundred similar patients received the two-week program of treatment, including the ether interviews. Of these, 50 were satisfactorily performing noncombat duty overseas one and two months after discharge from the hospital.

SUMMARY

A technic of administering ether to the psychiatric patient is described.

Ether was found to have the following advantages: it produced an excessive emotional response and maintained a useful hypnotic state for abreaction.

An interview under ether was a quick and useful method of surveying the conflicts of neurotic patients coming to an Army general hospital from combat.

In the treatment of 100 such patients in France, selected for two weeks of psychotherapy, ether interviews were found to be a significant adjunct to treatment.

ENHANCING THE RIBOFLAVIN CONTENT OF MARE'S MILK*

ARTHUR D HOLMES, PH D †

AMHERST, MASSACHUSETTS

ALTHOUGH cow's milk is generally considered one of the best natural sources of riboflavin, Holmes and his co-workers,¹ in a study of the vitamin content of mare's milk, found that draft (Percheron) mares produced milk containing extremely little riboflavin. The riboflavin levels varied from 0.05 to 0.20 mg per liter of milk, with averages of 0.09, 0.11, and 0.13 mg for the three mares used in the study. These values were less than one tenth those found for milk produced by cows that grazed in the same pastures and were fed hay grown in the same or adjacent fields to those that provided hay for the mares. Whether this difference in the riboflavin content of milk is related to the type of digestive tract of the two species — the cow is a ruminant, whereas the mare is a nonruminant — or whether some other factor is responsible is not known. Bechdel and his co-workers² and McElroy and Goss³ demonstrated that cows synthesize vitamin B in the rumen. Wegner et al.⁴ and Hunt and his associates⁵ showed that these animals can synthesize riboflavin in the rumen. The amount that can be synthesized is influenced by the type of ration, corn being particularly favorable for the rumen synthesis of riboflavin. Since mares have no rumen, they cannot add to their milk riboflavin produced by this type of bacterial synthesis.

Until foals begin eating hay, grass and concentrates, the mare's milk is the total source of riboflavin. Hence, the low riboflavin content of mare's milk naturally raised a question concerning its adequacy for supplying the riboflavin requirements of rapidly growing foals. The literature that was consulted contained, however, no information concerning the riboflavin nutrition of young foals, and this study was undertaken to accumulate additional data regarding the possibility of increasing the riboflavin content of mare's milk by feeding crystalline riboflavin ‡

EXPERIMENTAL PROCEDURE

Three Percheron mares were available for this study. They were normal, active, well developed animals. Mare 1 was seven years old, weighed 1900 pounds and produced four foals, Mare 2 was fourteen years of age, weighed 1800 pounds and had produced ten foals, and Mare 3 was five years old, weighed 1430 pounds and had produced her first foal.

None of the mares had been harnessed since the last foals were born. Accordingly, their food was utilized solely for their and the foals' body needs.

The experiment with Mares 1 and 2 was conducted during the summer months. During the night the mares received pasturage of rapidly growing green grass. During the day they were confined in a cool, shaded barn away from flies. The daytime feeding consisted of good-quality July-30-cut hay, mixed timothy, alfalfa and clover, three or four quarts of crushed oats and six or eight medium-sized ears of well cured white dent corn. The experimental period for Mare 3 was late winter and early spring, and her ration consisted of the same amounts of crushed oats and whole corn, with all the hay she desired.

Since riboflavin is only slightly soluble in water, a large volume of water would have been required for dissolving appreciable amounts of riboflavin and it would have been difficult to administer large amounts of liquid quantitatively. Accordingly, it was decided to feed the riboflavin in dry form. Since horses are particularly fond of sugar, this was used as a base. To prevent undesirable separation, both the sugar and the riboflavin crystals were ground to 100-mesh fineness and intimately mixed. The mixture was placed in No. 2 hard gelatin capsules, which were one third the size of a kernel of corn and somewhat larger than a crushed oat kernel. Thus, the amount of riboflavin contained in an individual capsule was relatively small. The capsules were mixed with the crushed oats. The mares were watched while they consumed their grain, and all the animals ate all the capsules.

During the sixteen-day prefeeding period, no crystalline riboflavin was fed. At its termination, Mare 1 was in the twenty-third week and Mare 2 in the thirteenth week of lactation. The riboflavin-containing capsules were administered for the next twenty-two days. During the first eight days each mare received 140 mg of riboflavin daily, and for the next three days 160 mg. The amount was then increased to 350 mg daily for nine days, after which the supply of riboflavin was nearly exhausted, and only 315 mg was fed for the next two days. Thus, each mare received a total of 5.26 gm of crystalline riboflavin during the twenty-two-day feeding period. The prefeeding period was twenty-four days for Mare 3, at that time she was in the seventeenth week of lactation. She was fed 100 mg of riboflavin daily for fourteen days, and 200 mg for the next fourteen days, after which she was unexpectedly removed.

*Contribution No. 579 Massachusetts Agricultural Experiment Station

†Research professor of chemistry, Massachusetts State College

‡The riboflavin was supplied through the courtesy of Dr. D. F. Green, Merck and Company, Incorporated, Rahway, New Jersey.

from the experiment and it was not possible to feed a larger amount or to assay her milk following the discontinuance of riboflavin feeding.

When the mares and foals were taken to the barn from the night pasture, they were separated. Two hours later milk was collected for riboflavin assay. During the early part of the study, even though the mares' udders contained milk after they had been separated from the foals, it was impossible to obtain any milk from them. Consequently, the foals were returned to their dams. As a result, the mares gave their milk and a sample was collected for assay while the foal was nursing. As the study progressed, the foals became less dependent on milk and the

four days, the riboflavin content of their milk suddenly increased to about four times that of the prefeeding period. In Mare 2, the maximum value was obtained on only one day, however, and the riboflavin content of the milk decreased day by day even before the riboflavin feeding was discontinued. The riboflavin content of the milk from Mare 1 likewise increased rapidly during the period of 350 mg daily, but this level was maintained so long as the maximum quantity of riboflavin was administered. Following the withdrawal of the crystalline riboflavin, the amount of riboflavin in the milk rapidly decreased, and when the fifty-four-day study was terminated, the riboflavin content of the milk of both mares had returned to the prefeeding level. During the prefeeding period the milk from Mare 3 averaged 0.13 mg per liter. The average for the fourteen days that she was fed 100 mg of riboflavin daily was 0.22 mg, and while she was fed 200 mg, 0.20 mg per liter. Since the experiment was unavoidably terminated at this point, no data were collected concerning the riboflavin content of the milk following riboflavin feeding.

Discussion

The data obtained in this study revealed that it was possible to increase the riboflavin content of milk from draft mares by feeding large amounts of crystalline riboflavin, but the increase was of short duration and the amount in the milk rapidly returned to normal levels. It is evident from these observations that the oral administration of riboflavin to mares is not an efficient method of increasing the foals' intake of riboflavin. Instead, natural riboflavin can be administered by feeding the foal as much skimmed cow's milk as it will consume.

In considering the low efficiency in supplying riboflavin to the foal through feeding crystalline riboflavin to the mare, it is interesting to note some of the results obtained by investigators who fed large amounts of vitamin A to animals or human subjects. Deuel and his associates⁷ succeeded in materially increasing the vitamin A content of milk from Holstein and Guernsey cows by feeding large amounts of vitamin A (shark-liver oil). In a later study, Hrubetz, Deuel and Hanley⁸ obtained a 200 per cent increase in the vitamin A content of human milk by feeding 100,000 international units of vitamin A per day to women from the sixth month of pregnancy to the termination of lactation, and the high level of vitamin A was maintained throughout lactation. In the present study, the increased riboflavin content of the mare's milk was extremely transient, but it could possibly have been maintained if massive doses of riboflavin had been administered throughout lactation. No information, however, is available concerning the requirements of young foals for riboflavin, even though Pearson, Sheybani and Schmidt⁹ state that riboflavin is a dietary essential for the horse, and Jones¹⁰ and Jones, Maurer and Roby¹¹ report

FIGURE 1 Effect of Feeding Riboflavin on Its Presence in Mare's Milk

mares became more accustomed to the procedure and could be milked satisfactorily while the foals were separated from them. As soon as the sample was collected, it was taken directly to the laboratory, where riboflavin assays were started at once without the milk's being cooled. As is obvious, the quantity of milk available for analysis did not represent twenty-four-hour samples.

The riboflavin assay was conducted by the fluorometric method described by Holmes and Jones⁶ for the assay of cow's milk.

RESULTS

The effect of the administration of crystalline riboflavin on the riboflavin content of mare's milk is shown graphically in Figure 1. The riboflavin content of the samples of milk obtained from each mare varied from day to day. During the prefeeding period, the riboflavin content averaged 0.13 mg per liter for Mare 1 and 0.09 mg for Mare 2. During the period in which the mares received 140 or 160 mg of riboflavin daily, there was little increase in the riboflavin content. In contrast, after the mares had been receiving 350 mg of riboflavin daily for

that ophthalmia and other deficiency symptoms develop when horses are fed riboflavin-deficient rations for considerable periods

SUMMARY

The average riboflavin content of milk from two normal draft mares was determined for a fourteen-day pre-experimental period. Subsequently, a total 5.26 gm of crystalline riboflavin was administered to each mare during a twenty-two-day feeding period. The riboflavin content of the milk increased about fourfold, but the increase was of short duration and the content soon returned to the pre-experimental level. When a third mare was fed 100 mg of riboflavin daily for fourteen days, the riboflavin content of the milk increased from 0.13 mg to 0.22 mg per liter, but feeding of 200 mg daily for the succeeding fourteen days produced milk that contained only 0.20 mg per liter. It is evidently more efficient to administer riboflavin directly to the foal than through the mare's milk, but the young foal's requirements for riboflavin are not generally known.

I am indebted to Mr Richard Nelson for his co-operation in caring for the mares, administering the riboflavin and collecting the samples of milk

MEDICAL PROGRESS

GOLD THERAPY IN RHEUMATOID ARTHRITIS*

CHARLES L SHORT, M D,† WILLIAM W BECKMAN, M D,‡ AND WALTER BAUER, M D§

BOSTON

THE ease of evaluation of a therapeutic agent varies in proportion to the natural course of the disease for which it is to be used. In subacute bacterial endocarditis, which, if untreated, carries a nearly uniformly fatal prognosis, therapeutic success is evidenced by an appreciable increase in the survival rate. In lobar pneumonia, the specificity of the sulfonamides and penicillin has been established by a significant reduction in the mortality rate and rapid alterations in the clinical manifestations. The appraisal of therapy, however, in a benign, self-limited disease such as the common cold has been extremely difficult even in well controlled investigations. The last and most puzzling group to evaluate comprises chronic diseases of widely varying course and prone to spontaneous, unpredictable remissions and exacerbations. Examples of this group include bronchial asthma, peptic ulcer and rheumatoid arthritis. Neverthe-

less, from time to time, new methods of treating rheumatoid arthritis are claimed to have, if not specificity, at least a definite effect on the course of the disease. The early enthusiasm for each procedure is sooner or later dampened by the publication of critical, well controlled studies with essentially negative results.¹⁻³ An exception is gold therapy, introduced nearly twenty years ago, although its acclaimed specificity has occasionally been challenged in recent years.

The purpose of this report is not to present an inclusive review of the subject, which has been adequately performed elsewhere,⁴⁻¹¹ but to attempt to determine from the available evidence whether gold salts should be regarded as specific, as fulfilling an intermediate, adjuvant function or as having no established value. The harmful potentialities of gold treatment, including its toxicity, and the danger that, by dependence on gold alone, constitutional treatment and indicated orthopedic measures may be neglected must be carefully weighed.

HISTORICAL DEVELOPMENT

Although gold has been found effective in certain experimental infections,¹² its clinical use in modern

*Publication No. 89 of the Robert W Lovett Memorial Foundation for the Study of Crippling Disease. Harvard Medical School.

times has been largely confined to patients with tuberculosis, lupus erythematosus of the discoid type and rheumatoid arthritis. Landé¹² and Pick¹⁴ in 1927 were the first to report on gold therapy in rheumatoid arthritis, but Forestier¹⁵⁻¹⁸ was responsible for its popularization in France and other European countries, England and finally the United States. His employment of gold in rheumatoid arthritis was founded on two now generally discredited premises that gold salts are effective in tuberculosis and that rheumatoid arthritis may be of tuberculous origin. The first British publication, by Slot and his co-workers¹⁹ in 1934, was followed by two American reports²⁰⁻²¹ in 1936. Since then, more than forty articles on chrysotherapy in rheumatoid arthritis have appeared in English, with conspicuously few adverse reports or opinions.^{20, 22-27}

MECHANISM OF ACTION

It may be stated at the outset that the mechanism of action of gold in rheumatoid arthritis is unknown and that the explanations offered rest entirely on hypothesis. Hartung²⁸ reported that the serums of patients receiving gold show a marked increase in bacteriostatic power against a strain of hemolytic streptococcus. This finding does not furnish an explanation of the mode of action of gold, since the etiology of rheumatoid arthritis, whether or not infectious, remains unknown. Others postulate a stimulation of the defense mechanisms of the body, presumably by deposition of gold in reticuloendothelial cells.²⁹ No evidence has been presented that gold has an analgesic effect or decreases joint swelling through diuresis, either of which might explain some of its favorable action. In view of the remissions in rheumatoid arthritis associated with intercurrent hepatic jaundice,³⁰ it has been suggested that the effect of gold is mediated by the production of liver damage, but demonstrable toxic effects on this organ have been rare, except in one series.⁴ Bayles and Riddell,³¹ in an attempt to find a common denominator for remissions associated with jaundice, pregnancy and gold, could demonstrate no increase in plasma lipids in gold-treated patients with rheumatoid arthritis. Finally, an impression has been gained from the literature^{32, 33} that patients exhibiting toxicity have nevertheless fared especially well so far as their arthritis was concerned. Such observations have led to the theory that the action of gold may depend on mild "protein shock," similar to the temporary ameliorating effect of intravenous typhoid vaccine.

PHARMACOLOGY

Knowledge of the clinical pharmacology of gold is largely derived from the extensive investigations of Freyberg and his co-workers,³⁴⁻³⁵ whose reports are freely utilized in this section. Although over twenty gold compounds have been used therapeutically,⁶⁻³⁶ only the preparations most frequently employed in recent years are discussed. All of them contain sulfur, but the gold content is believed to determine their therapeutic activity. Gold sodium thiosulfate (Allochrysine, Crisalbine and Sanocrysin) and gold sodium thiomalate (Myochrysine) are water-soluble salts. The former contains 37 per cent of gold and may be administered intravenously or intramuscularly, whereas the latter contains 50 per cent and is given intramuscularly. Both are absorbed with uniform rapidity and are regularly although slowly excreted. Gold thioglucose (Solganol B), although soluble in water, is administered in oil. This accounts for its slower and often variable absorption and the lower gold plasma levels observed, as compared with those seen in patients receiving other compounds of similar gold content (50 per cent). The same observation is true to an even greater extent of calcium thiomalate, which is insoluble in water, dispensed in oil suspension and also contains 50 per cent gold. Both salts, although apparently less toxic in the early stages of treatment owing to faulty absorption, may give rise to late toxicity, which is liable to be persistent and severe because of a relatively greater retention of gold associated with slow and irregular excretion.

Animal experiments suggest that the low plasma levels attained clinically with colloidal gold sulfide (Aurol-sulfide, containing 87 per cent of gold) are due to rapid disappearance of gold from the blood stream associated with phagocytization in reticuloendothelial cells, especially those of the liver and spleen.³⁵ Toxicity is thereby prevented, but opportunity for therapeutic action is minimized. In choosing a preparation for therapeutic use, the physician can logically adopt the conclusion that a water-soluble preparation should more readily reach the site of its action and, in addition, furnish warning of impending toxicity before the administration of an excessive amount.

Following absorption, gold is carried in an undetermined form in the protein fraction of the plasma. Its excretion is largely through the urine, although some appears in the stools. In spite of increasing accumulation in the body with repeated equal doses, plasma concentration remains relatively constant and excretion is increased only on the day of injection. Although the actual site of retention in the human body is not known, it is of practical importance that 70 to 80 per cent of the gold administered in a given period may be retained. Excretion may continue for months after the last injection, and may endure roughly in proportion to the amount given and to the rapidity of administration. Opportunity is thus presented for delayed and prolonged toxic manifestations. Snyder³⁷ cites a patient who developed a dermatitis that began one month after the last injection and persisted for nine months, she was still excreting gold five hun-

dred and ten days after treatment had been concluded

It was mentioned above that water-soluble compounds are preferable for therapeutic use. In view of their rapid absorption, no advantage is gained by intravenous injections, which may cause a sudden — possibly toxic — increase in concentration in the kidneys. The most effective and safest scheme of dosage remains to be determined. The trend in recent years has been to decrease the maximum weekly dose from 50 mg of metallic gold to 25³⁸⁻⁴⁰ or even 12.5 mg.⁴¹ It is believed that a smaller amount of gold in the body at any one time reduces the incidence, severity and duration of toxic manifestations.³⁵ Irrespective of the weekly dosage, a total of 500 mg of metallic gold usually comprises one course, the interval between courses varying from one to three months. The practitioner is confronted with a dilemma at this point. He must weigh the possibility of delayed toxicity against the possibility that the disease will relapse with discontinuance of therapy. To overcome this difficulty, it has been suggested that small maintenance doses between courses be used^{36, 41, 42} or that the drug be given continuously in small amounts for a prolonged period.⁴¹

Toxicity

The toxicity of gold compounds is fully described in a number of papers,^{4, 43, 44} including Sundelin's⁶ exhaustive monograph. The reported rates of toxicity range from 17 to 77 per cent, an average of 1 patient in 4 suffering some untoward effect. These reactions may involve almost every organ of the body, but the skin and mucous membranes (usually that of the mouth) are by far the most susceptible. Serious reactions include exfoliative dermatitis, hepatitis, colitis, purpura, agranulocytosis, encephalitis³⁷ and peripheral neuritis. An estimate made from a combined series of 1800 cases showed that 1 patient in 30 had a severe reaction and that 1 in 200 died as a result of gold therapy.³⁵

In one series, a reduction in incidence and severity of toxic reactions was ascribed to the use of smaller dosages³⁶; in another group similarly treated, however, there were 3 cases of exfoliative dermatitis and 2 of encephalitis among 100 patients.³⁸ There may be merit in beginning a course of therapy with small, gradually increasing amounts of gold so that sensitivity may be detected earlier and the reaction may be less severe and not so prolonged because of the presence of less gold in the body. Unfortunately, toxic manifestations may appear at the end of a course, may be delayed until the second or third course, or may even show up many months after the last injection. Toxicity is not related to the plasma level of gold, so that chemical control of administration cannot be employed.³⁵

Owing to the unpredictability of reactions, it is believed that, with the exception of renal damage,

they occur as an expression of sensitivity, either already present³⁷ or acquired during the administration of gold. Patch or intradermal tests are not helpful in determining which patients may be sensitive.^{35, 45} Careful clinical and laboratory examinations prior to the institution of treatment and before each dose, with special attention to the kidneys, liver, blood-forming organs and skin, are the only available safeguards. Urticaria, eczema and colitis furnish additional contraindications to the use of gold.

Treatment of the reaction, once started, has not been successful, although sodium thiosulfate, vitamins C and D, a high-calcium diet and shifting the acid-base equilibrium in either direction have been used.³⁵ A trial of BAL (British Anti-Lewisite), which has proved effective in arsenic intoxication,⁴⁶ is indicated. In spite of all precautions, the administration of gold carries a constant risk of a disabling toxic reaction. This fact must be kept in mind in any discussion of therapeutic results.

SELECTION OF PATIENTS

It is generally agreed that the effectiveness of gold in arthritis is limited to the rheumatoid type. There is no indication for its use in degenerative joint disease, gouty arthritis or arthritis associated with specific infections. Whether or not ankylosing spondylitis is regarded as a variety of rheumatoid arthritis, its treatment with gold has, except for one report,¹⁸ proved disappointing and therefore is usually not advised. Neither the age of the patient nor the duration of the disease is a factor in the selection of cases for treatment. Active arthritis should of course be present, but Forestier¹⁸ states that symptomatic relief may be obtained in apparently burnt-out cases with marked deformity. Early cases usually respond more favorably than those of longer duration, but on this point there is also some disagreement.^{5, 47} As pointed out below, patients in the early months of their first attack of rheumatoid arthritis are likelier to have spontaneous remissions irrespective of the treatment employed.⁴⁸ Therefore, a physician should not be criticized for delaying the use of a potentially dangerous drug at this stage of the disease.

RESULTS OF TREATMENT

Thirty-five papers in the English language on the results of gold therapy in rheumatoid arthritis have been reviewed. It is not possible to present the combined figures owing to the varying criteria utilized in judging improvement and the failure of some authors to state the degree of benefit obtained. An idea of the general trend may be gained, however, from the following percentages: gross improvement, of any degree — 84.0 per cent of 1943 patients, noteworthy objective improvement (usually a combination of the arrested and markedly improved group) — 59.3 per cent of 2924 patients,

and arrested, cured or in remission — 22.6 per cent of 1825 patients. In general, a fall in the sedimentation rate paralleled the degree of improvement, but in some patients who showed a marked clinical gain the rate was unchanged or rose.⁴⁹ In one study, in which untreated controls were used, an apparently greater tendency to a lowered rate was evidenced in all the gold-treated patients, whether or not they were clinically improved.⁵⁰

The rates of improvement cited in the preceding paragraph are impressive, but several criticisms and queries are immediately suggested. The first concerns the selection of patients. Had they been observed sufficiently long prior to chrysotherapy to make a coincidental remission unlikely? Were the patients hospitalized or receiving other treatment? The second criticism pertains to the course of untreated rheumatoid arthritis when it is untreated or when only general measures are used. Was a control group utilized, or were control series available in the literature for comparison? Finally, was the improvement held so that the use of the word "arrest" rather than "remission" was justified, or did a large proportion of patients rapidly revert to their former state? In six reports, the patients selected were considered "refractory" and received no other treatment than gold.^{26 40 45 51 52} When the available figures from these reports are combined, 41.6 per cent of the patients showed marked objective improvement, and 8.3 per cent entered on a remission. These percentages are definitely less striking than those for the combined series (59.3 and 22.6 per cent respectively) and suggest that spontaneous remissions are a factor in the more favorable results given for unselected series.

In two series the authors used comparable control groups. Ellman, Lawrence and Thorold⁵³ gave to one group of 30 patients two courses of gold, with an average weekly dose of 200 mg of Solganol B, to another, an average weekly dose of 100 mg, and to a third, a control group, injections of sterile oil. Although 76 per cent of the last group showed some improvement, compared to a total of 94 per cent in the two treated groups, in 37 per cent of the patients who received gold the disease became asymptomatic and the sedimentation rate returned to normal. These last results were realized in only 1 control patient. Objective improvement was also recorded more frequently in the treated patients, but the differences were not so striking. Those subjects receiving the larger dosage of gold showed a greater degree of improvement, but there was a corresponding rise in toxicity, with 1 death from agranulocytosis. Fraser⁵⁰ also divided his patients into two groups of about 50 each, one receiving an average weekly dosage of 100 mg of Myochrysine and the other an ampule containing the same constituents but without gold. Until the final observations were recorded at the end of a year, neither the author nor the patients knew which preparation had been

administered. The results of treatment showed that 82 per cent of the treated group and 45 per cent of the controls had obtained some degree of improvement but that this was "great" or "moderate" in 63 per cent of the former and in only 21 per cent of the latter. The conclusion is drawn by Fraser that the good results claimed for gold therapy by the majority of observers are unjustifiably high owing to the lack of adequate controls. The authors of these two papers recognize that the short period of observation, nine months and a year respectively, constitutes the chief objection to drawing final conclusions from their studies. They believe, however, that their results show that the improvement rate is definitely increased in a group of patients with rheumatoid arthritis by the administration of gold.

It is also worth while to compare the results recorded from gold with those reported for patients receiving other methods of therapy. Steinbrocker⁴⁸ recently emphasized the fact that rheumatoid arthritis most frequently pursues a fluctuant course and that the disease in any stage may recede and become inactive. Furlong⁵⁴ and others express the belief that, regardless of so-called "specific measures," 60 to 70 per cent of patients receiving general treatment show improvement. Sashin, Spanbock and Kling,⁵¹ however, observed more favorable results in their gold-treated patients than in those previously treated by other methods. In 1938, Thompson, Wyatt and Hicks⁵⁵ reported on 274 patients treated in various ways (including vaccines, removal of foci of infection and transfusions), 12.8 per cent were not benefited, 76.5 per cent were moderately or markedly improved, and 6 per cent became entirely well. In a later paper,⁴⁰ 26 patients who had been refractory to the treatment employed in the 1938 report were given gold, 19 of these showed improvement, and 8 became quiescent. This is a small series, and comparable results were not obtained in a similar study of 50 patients by Snyder, Traeger and Kelly.⁵²

In 1937, before gold had been used in the medical clinic of the Massachusetts General Hospital, a follow-up study was made of 274 patients who had been observed for periods ranging from six months to seven years. These patients had received only general and orthopedic treatment and, except for a small number, had been hospitalized only for a few weeks of study. The results are shown in Table 1. Improvement was not recorded unless it was objective and definite. Patients pursuing a fluctuating course with minor variations were placed in the stationary group. The figures of 16.4 per cent for those in remission and of 52.9 per cent for those improved may be informatively compared with the results reported from the combined series of gold-treated patients in the literature. 22.6 per cent in remission and 59.3 per cent with definite objective improvement. In addition, corroboration was ob-

dred and ten days after treatment had been concluded

It was mentioned above that water-soluble compounds are preferable for therapeutic use. In view of their rapid absorption, no advantage is gained by intravenous injections, which may cause a sudden — possibly toxic — increase in concentration in the kidneys. The most effective and safest scheme of dosage remains to be determined. The trend in recent years has been to decrease the maximum weekly dose from 50 mg. of metallic gold to 25³⁸⁻⁴⁰ or even 12.5 mg.⁴¹ It is believed that a smaller amount of gold in the body at any one time reduces the incidence, severity and duration of toxic manifestations.³⁵ Irrespective of the weekly dosage, a total of 500 mg. of metallic gold usually comprises one course, the interval between courses varying from one to three months. The practitioner is confronted with a dilemma at this point. He must weigh the possibility of delayed toxicity against the possibility that the disease will relapse with discontinuance of therapy. To overcome this difficulty, it has been suggested that small maintenance doses between courses be used^{35, 41, 42} or that the drug be given continuously in small amounts for a prolonged period.⁴¹

TOXICITY

The toxicity of gold compounds is fully described in a number of papers,^{4, 43, 44} including Sundelin's⁶ exhaustive monograph. The reported rates of toxicity range from 17 to 77 per cent, an average of 1 patient in 4 suffering some untoward effect. These reactions may involve almost every organ of the body, but the skin and mucous membranes (usually that of the mouth) are by far the most susceptible. Serious reactions include exfoliative dermatitis, hepatitis, colitis, purpura, agranulocytosis, encephalitis³⁷ and peripheral neuritis. An estimate made from a combined series of 1800 cases showed that 1 patient in 30 had a severe reaction and that 1 in 200 died as a result of gold therapy.²⁵

In one series, a reduction in incidence and severity of toxic reactions was ascribed to the use of smaller dosages³⁵; in another group similarly treated, however, there were 3 cases of exfoliative dermatitis and 2 of encephalitis among 100 patients.³³ There may be merit in beginning a course of therapy with small, gradually increasing amounts of gold so that sensitivity may be detected earlier and the reaction may be less severe and not so prolonged because of the presence of less gold in the body. Unfortunately, toxic manifestations may appear at the end of a course, may be delayed until the second or third course, or may even show up many months after the last injection. Toxicity is not related to the plasma level of gold, so that chemical control of administration cannot be employed.³⁵

Owing to the unpredictability of reactions, it is believed that, with the exception of renal damage,

they occur as an expression of sensitivity, either already present³⁷ or acquired during the administration of gold. Patch or intradermal tests are not helpful in determining which patients may be sensitive.^{35, 45} Careful clinical and laboratory examinations prior to the institution of treatment and before each dose, with special attention to the kidneys, liver, blood-forming organs and skin, are the only available safeguards. Urticaria, eczema and colitis furnish additional contraindications to the use of gold.

Treatment of the reaction, once started, has not been successful, although sodium thiosulfate, vitamins C and D, a high-calcium diet and shifting the acid-base equilibrium in either direction have been used.³⁵ A trial of BAL (British Anti-Lewisite), which has proved effective in arsenic intoxication,⁴⁶ is indicated. In spite of all precautions, the administration of gold carries a constant risk of a disabling toxic reaction. This fact must be kept in mind in any discussion of therapeutic results.

SELECTION OF PATIENTS

It is generally agreed that the effectiveness of gold in arthritis is limited to the rheumatoid type. There is no indication for its use in degenerative joint disease, gouty arthritis or arthritis associated with specific infections. Whether or not ankylosing spondylitis is regarded as a variety of rheumatoid arthritis, its treatment with gold has, except for one report,¹⁸ proved disappointing and therefore is usually not advised. Neither the age of the patient nor the duration of the disease is a factor in the selection of cases for treatment. Active arthritis should of course be present, but Forestier¹⁹ states that symptomatic relief may be obtained in apparently burnt-out cases with marked deformity. Early cases usually respond more favorably than those of longer duration, but on this point there is also some disagreement.^{5, 47} As pointed out below, patients in the early months of their first attack of rheumatoid arthritis are likelier to have spontaneous remissions irrespective of the treatment employed.⁴⁸ Therefore, a physician should not be criticized for delaying the use of a potentially dangerous drug at this stage of the disease.

RESULTS OF TREATMENT

Thirty-five papers in the English language on the results of gold therapy in rheumatoid arthritis have been reviewed. It is not possible to present the combined figures owing to the varying criteria utilized in judging improvement and the failure of some authors to state the degree of benefit obtained. An idea of the general trend may be gained, however, from the following percentages: gross improvement, of any degree — 84.0 per cent of 1943 patients, noteworthy objective improvement (usually a combination of the arrested and markedly improved group) — 59.3 per cent of 2924 patients,

and arrested, cured or in remission — 22.6 per cent of 1825 patients. In a later paper,⁴⁰ 26 patients who had been refractory to the treatment employed in the 1938 report were given gold, 19 of these showed improvement, and 8 became quiescent. This is a small series, and comparable results were not obtained in a similar study of 50 patients by Snyder, Traeger and Kelly.⁵⁵

In 1937, before gold had been used in the medical clinic of the Massachusetts General Hospital, a follow-up study was made of 274 patients who had been observed for periods ranging from six months to seven years. These patients had received only general and orthopedic treatment and, except for a small number, had been hospitalized only for a few weeks of study. The results are shown in Table 1. Improvement was not recorded unless it was objective and definite. Patients pursuing a fluctuating course with minor variations were placed in the stationary group. The figures of 16.4 per cent for those in remission and of 52.9 per cent for those improved may be informatively compared with the results reported from the combined series of gold-treated patients in the literature. 22.6 per cent in remission and 59.3 per cent with definite objective improvement. In addition, corroboration was ob-

tained of the likelihood of remission in early cases. Of 51 patients first seen within six months of the onset of their disease, 25 (49 per cent) were found to be in remission.

The tendency of a patient with rheumatoid arthritis who has shown improvement after one course of gold to relapse has been stressed since the original reports of Forestier.¹⁶⁻¹⁸ Certain authors found that further treatment again brings about improvement in the majority of cases, with a net

TABLE 1 *Results of General and Orthopedic Treatment in Rheumatoid Arthritis*

STATUS OF DISEASE	NO OF CASES	PERCENTAGE
Improved	145	52.9
In remission	45	16.4
Moderately improved	33	12.0
Slightly improved	67	24.5
Stationary	79	28.8
Worse	50	18.3
Total	274	

relapse rate of about 20 per cent,^{4, 8, 19} but Freyberg³⁵ states that retreatment has proved less satisfactory. The most recent study of relapses following gold therapy was presented at the 1946 meeting of the American Rheumatism Association by Ragan and Tyson,⁴² who reported on follow-up studies for at least three years of 142 patients, 50 per cent of whom had shown objective improvement following one or more courses of gold. Only 13 per cent had maintained their improvement for periods ranging from forty-five to seventy-eight months, and a five-year cure was obtained in only 9 cases. About

had been progressive or in a steady state for at least six months. Otherwise, they were unselected and represented a cross-section of the disease. There were 15 males and 32 females in the series, with ages ranging from eleven to sixty-eight years. The duration of the disease was under five years in about half the patients, but two years or under in only 5 and less than one year in none. The total severity of the disease was classified as follows: mild, 7; moderate, 31; and marked, 9. Most patients received Myochrysine, with a maximum weekly dosage of 100 mg. An attempt was made to give each patient at least two courses, each totaling 1 gm of the drug. In 12, the treatment had to be stopped on account of toxicity before a full course had been given. The remaining 35 received a total of sixty-seven courses. Only a few of the patients receiving gold were hospitalized during treatment, but many of the others continued with extra rest, analgesics, a good diet and exercises, although general treatment was not stressed during this period.

The results of therapy are shown in Table 2, along with the rate of relapse following treatment, on the basis of the most recent follow-up study of patients showing improvement. In each case, any improvement recorded was objective and definite, so that the results may be compared with the control series in Table 1. Some improvement was observed in nearly the same proportion of patients treated with gold as in the controls, but none of the gold-treated patients entered on a remission. This difference might be expected from the fact that the patients receiving gold were selected for resistance to ordinary forms of treatment. From a

TABLE 2 *Results of Gold Therapy in Rheumatoid Arthritis*

STATUS OF DISEASE	NO OF CASES	PER CENTAGE	NO OF RELAPSES	NET IMPROVEMENT	
				NO OF CASES	PER CENTAGE
Improved	21	60	13	8	23
In remission	0	0	0	0	0
Moderately improved	7	20	6	1	3
Slightly improved	14	40	7	7	20
Stationary or worse	14				
Total	35				

75 per cent of patients who had experienced objective improvement had relapsed, although usually not to a condition as severe as their original disease. As mentioned above these authors hope to lessen the rate of relapse by small maintenance doses at intervals of several weeks. From these figures, the conclusion is inescapable that gold therapy, as usually administered, exerts at best a transitory effect on the course of rheumatoid arthritis.

Experience at the Massachusetts General Hospital with gold therapy in rheumatoid arthritis is limited to 47 patients, in all of whom the disease

study of the two tables, it is difficult to find evidence that gold therapy exerted any noteworthy effect on the course of the disease.

Sedimentation rates were determined at regular intervals in all cases. The results roughly paralleled the degree of clinical improvement, with normal values reached in all but 1 of the moderately improved patients, but an appreciable fall took place in only half of those showing slight improvement. The incidence of toxicity was high. In addition to the 12 in whom treatment had to be stopped during the first course, in 5 the dosage was inter-

rupted during the second or third course, and another 5 suffered from delayed manifestations of toxicity, sometimes months after the course had been finished. One patient developed a mild purpuric eruption after 0.9 gm of Myochrysine, when treatment was stopped, over four months after the last injection, purpura reappeared in a generalized form, with bleeding from the gums and nose. Platelets were found to be absent from the blood smear. In spite of repeated transfusions, the patient continued to show evidence of widespread bleeding, and death took place in five weeks. At autopsy bilateral subdural hematomas were found to be the principal cause of death.

CONCLUSIONS

The first question that this report attempted to answer is whether gold therapy may be regarded as a specific and constantly effective treatment for rheumatoid arthritis. That the activity of the disease process is reversible is shown both by spontaneous remissions and by those encountered in pregnancy and intercurrent jaundice. From the small percentage of patients in the literature in whom the disease was arrested subsequent to gold treatment and from our own experience, the answer seems evident that gold cannot rightfully be included in the select group of specific agents available in medical therapy, such as the sulfonamides and penicillin in bacterial infections and the arsenicals and heavy metals in syphilis. Corroboration of this conclusion is furnished by the statements of a number of others who have had experience with gold therapy and who believe that this method should supplement general measures or constitute only a part of a broad therapeutic program.³⁵⁻⁵³

It is more difficult to furnish a categorical answer to the question whether gold is of some benefit to the patient with rheumatoid arthritis and whether its use is therefore justified in a patient failing to respond to conservative measures. Two control studies apparently demonstrate an additive therapeutic effect on the part of gold during relatively brief periods of observation.⁵⁰⁻⁵³ Otherwise, the results obtained with gold may be approximated with those in patients given general, conservative treatment. A careful follow-up study of patients improving during gold therapy reveals a high percentage of relapses, so that the net gain is slight. There is even an indication that the natural, fluctuant course of the disease is largely responsible for the results reported in such cases. The burden of proof is still on the proponents of gold therapy to demonstrate by adequately controlled studies with a follow-up of three to five years that a significant effect is exerted on the course of rheumatoid arthritis by the administration of gold salts.

Finally, the unpredictable, unpreventable and at times irremediable toxic manifestations of gold therapy cannot be overlooked. If the specificity

of gold were established, this risk would be justifiable in a disease that bears the implications of lasting invalidism. With the case as yet unproved for its place as a palliative or adjuvant remedy in rheumatoid arthritis, the hazard of this form of therapy should furnish the decisive argument against its general use.

MASSACHUSETTS MEDICAL SOCIETY

PROCEEDINGS OF THE COUNCIL

Annual Meeting, May 21, 1946

THE annual meeting of the Council was called to order by the president, Dr Reginald Fitz, Suffolk, on Tuesday, May 21, 1946, at 7 00 p m, in the Georgian Room of the Hotel Statler, Boston, 191 councilors (Appendix No 1) were present

In opening the meeting the President read the following obituary

The President regrets to report the death of John Joseph Elliott, a councilor from the Norfolk District He was in his fiftieth year

Dr Elliott received his degree from the Hahnemann Medical College in 1921 in Pottsville, Pennsylvania, where he spent his early days, he attained high distinction as an athlete, excelling in football, basketball, baseball and track When he received his medical diploma he came to Boston and here he remained, after serving an internship and residency at the Massachusetts Memorial Hospitals In 1923 he was appointed to the staff of that institution and was promoted in the course of twelve years from the rank of second assistant obstetrician to that of obstetrician

Perhaps his flair for athletics enabled him to understand how the minds of young men react In any event, he soon demonstrated outstanding ability as a teacher, became assistant in the Department of Obstetrics at Boston University in 1926, and was advanced through the grades of instructor and assistant professor until finally, in 1944, he was created associate professor

He was a successful, hard-working physician, but in addition to leading a busy life as practitioner and teacher, he found time in which to cultivate hobbies in the field of sport He was a recognized authority on the technical phases of basketball, track and baseball, he was consulting physician to the Boston College football team, he stimulated interest, locally, in pigeon racing, and he achieved national fame as horseman and owner of champion ponies

He became a fellow of the Massachusetts Medical Society in 1926, serving on the Council during 1940, 1941 and 1942, and from 1945 until his death He despised unfairness in any form, his judgment always was sound and unbiased, and thus he was a valuable member

Besides being a fellow of the Massachusetts Medical Society and the American Medical Association, he belonged to the American College of Surgeons, the New England Obstetrical and Gynecological Association and the West Roxbury Medical Club

Dr Elliott is survived by his widow, two sons and a daughter

The President asked the councilors to stand for one minute in silent tribute to the memory of Dr Elliott

In accordance with the vote of the Council in February, 1946, the President announced the following appointments

Committee to Assist the Council on Medical Education and Hospitals of the American Medical Association in the Provisional Approval of Certain Massachusetts Hospitals

Robert T Monroe, Norfolk, chairman
H Quimby Gallupe, Middlesex South
Walter G Phippen, Essex South
Michael A Tighe, Middlesex North
Charles F Wilinsky, Suffolk

Committee to Review the Matter of Malpractice Insurance

Carl Bearse, Norfolk, chairman
William J Brickley, Suffolk
Edwin D Gardner, Bristol South
Daniel B Reardon, Norfolk South
Guy L Richardson, Essex North

Committee on Postgraduate Assembly

Leroy E Parkins, Suffolk, chairman
Harold G Giddings, Middlesex South
Frederick S Hopkins, Hampden
Charles J Kickham, Norfolk
Robert N Nye, Suffolk

The President asked for confirmation of these appointments It was so ordered by vote of the Council

The Secretary submitted the record of the meeting of the Council held on February 6, 1946, as published in the May 2, 1946, issue of *The New England Journal of Medicine*, and moved its adoption This motion was seconded, and it was so ordered by vote of the Council

REPORT OF THE TREASURER

This report (Appendix No 2) was offered by Dr Eliot Hubbard, Jr, as published in the pamphlet of

advance information. He moved its adoption. This motion was seconded and it was so ordered by vote of the Council.

REPORTS OF COMMITTEES

Executive Committee — Dr. Michael A. Tighe, Middlesex North, secretary.

The Secretary submitted the report (Appendix No. 3) as published in the circular of advance information and moved its acceptance. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Auditing Committee — Dr. William B. Robbins, Suffolk, chairman, and Dr. Arthur W. Carr, Plymouth.

This report, which was offered by the chairman, is as follows:

The Auditing Committee appointed the firm of Hartshorn and Walter, accountants and auditors to audit the books and accounts of the Massachusetts Medical Society. This audit and account are hereby approved by us.

The analysis of the revenues and expenses of the Society, and the balance sheet of the condition of the funds of the Society, have been inspected and approved by us.

Dr. Robbins moved the adoption of the report. This motion was seconded, and it was so ordered by vote of the Council.

Committee on Arrangements — Dr. Roy J. Heffernan, Norfolk, chairman.

This report, which is as follows, was offered by the chairman:

The program of the annual meeting is our final report. You will be pleased to note that, in addition to the usual scientific program, the committee has revived some of the pleasant antebellum features, namely, the activities for the distaff side and the annual golf tournament.

It should be emphasized that the commercial exhibits supply the wherewithal for our annual meeting. All members are urged to visit these exhibits frequently.

I wish to thank the other members of the Committee on Arrangements for their loyal and efficient co-operation. Our chief worry during the past year was that something might happen to Mr. Robert Boyd before our plans were consummated. I cannot imagine how the committee could function without his gracious assistance. We are very grateful to him.

Dr. Heffernan, in offering the report, said that it contained one recommendation that the fellows be urged to visit the commercial exhibits several times during the annual meeting.

He moved the adoption of the report and the recommendation contained in it. This motion was seconded by a councilor.

The President called on the Secretary for such comment as the Executive Committee might wish to make regarding this report. The Secretary said that the Executive Committee approved of the recommendation contained in the report and, in the furtherance of its objective, recommended additionally that the *New England Journal of Medicine* carry suitable references to these exhibits and that the several chairmen who preside over the exercises of the annual meeting be instructed to call, at least

twice daily, the attention of the gathering to them and to the importance of paying them a visit.

These additional recommendations, having been accepted by the maker of the motion and its seconder, became part of the original motion. The motion was adopted by vote of the Council.

Committee on Medical Defense — Dr. Arthur W. Allen, Suffolk, chairman.

In the absence of the chairman the Secretary offered the report, which is as follows:

We now have five malpractice suits pending. No new cases developed during the past year. Six cases were disposed of during the year.

The total bills for legal services and disbursements for the year 1945 amounted to \$571.67.

The Secretary moved the acceptance of the report. This motion was seconded, and it was so ordered by vote of the committee.

Committee on Medical Education — Dr. Robert T. Monroe, Norfolk, chairman.

This report (Appendix No. 4), as it appeared in the circular of advance information, was submitted by the chairman. He added that it was purely informational. He moved adoption of the report. This motion was seconded by a councilor.

The President called on the Secretary for such comment as the Executive Committee might wish to make regarding the report. The Secretary reported for the Executive Committee, as follows:

This report is an excellent factual study of correlated material brought together from many sources. Its conclusions are soundly drawn. The Executive Committee is aware that the stimulus to the resolution offered by Dr. Morgan, by which the Council authorized this study, came about largely as the result of inquiry by members of the Massachusetts Legislature as to the need of additional medical schools in Massachusetts.

Because this report now makes such information readily available, the Executive Committee in addition to recommending that the report be accepted by the Council, further recommends that the Council specifically direct the attention of the Committee on Legislation to the report, for such use as this latter committee may deem wise. In so directing the attention of the Committee on Legislation to this report, the Executive Committee points out that Table 4, as it relates to the rejections listed, without further explanation, might be subject to serious misunderstanding. In this connection the Executive Committee would have the Council and the Committee on Legislation know that most candidates apply simultaneously to many medical schools, and that those rejected by one school frequently find places in another. The committee has it on competent authority that a little over 50 per cent of all applicants ultimately find places in some medical school.

The maker of the motion and the seconder having accepted the recommendation of the Executive Committee, it became a part of the original motion, which was adopted by vote of the Council.

Committee on Publications — Dr. Richard M. Smith, Suffolk, chairman.

This report (Appendix No. 5) was submitted as published in the circular of advance information.

The chairman, in offering the report, called the Council's attention to the fact that we are now in the twenty-fifth year during which the *New England Journal of Medicine* has been operated by the Massachusetts Medical Society.

The report stated that Dr John B Youmans, formerly chief of the Nutrition Branch of the Office of the Surgeon General and associate professor of medicine at Nashville, Tennessee, had been selected to deliver the Shattuck Lecture during the annual meeting of the Society in 1946, that a directory of the fellows had been published during the year (1945) and that the accounts of the *Journal* had been audited and found to be in order.

The report, in calling attention to the excellent record of the *Journal* during the last year, spoke highly of the managing editor, Dr Robert N Nye, the assistant editor, Miss Davies, the associate editors and the members of the Editorial Board.

He quoted from the report of the managing editor to the effect that there was a substantial net increase in the circulation during the year 1945 and not only that the *Journal* had not used any of the monies appropriated by the Society for its use in 1945 but also that on December 31, 1945, it paid to the Treasurer of the Society the sum of \$22,800.00. The report said that the pagination of the *Journal* had been increased and that the stock used was heavier, all of which was made possible by the removal of governmental limitations on paper.

The report said that the difficulties in the matter of printing were still present, and that the increased circulation and the shifting of addresses brought about by the war present a major problem. If the *Journal* is to function properly, additional office space must be provided.

Dr Smith moved the adoption of the report. This motion was seconded, and it was so ordered by vote of the Council.

Committee on Public Health—Dr Roy J Ward, Worcester, chairman.

This report (Appendix No 6) was offered by the chairman as published in the circular of advance information. He pointed out that it contained a recommendation that the President be authorized to take the initiative in aiding the four district societies concerned in selecting suitable representation on the Greater Boston Nursing Council. He moved the adoption of the report and the recommendation contained in it. This motion was seconded.

The President called on the Secretary for such comment as the Executive Committee might wish to make regarding this report. The Secretary reported for the Executive Committee, as follows:

The Executive Committee notes that this report contains a recommendation to the effect that the president of the Society be authorized to take the initiative in aiding the four district societies concerned in selecting suitable representation on the Greater Boston Nursing Council. The Executive Committee disapproves of this recommendation.

It believes that because of the Society's statewide character it should not associate itself with an organization that is purely sectional in its scope and purposes. The Executive Committee recommends in this connection that the Council reaffirm its stand in this matter as taken on October 6, 1937.

The Executive Committee further recommends that the Council instruct the Secretary to write to Miss Tracy, of the Greater Boston Nursing Council, advising her of the Society's sympathetic interest in this matter and recommending that she make contact with the district societies concerned.

He moved, by way of amending the motion, the adoption of the recommendations of the Executive Committee. This motion was seconded.

Dr Elmer S Bagnall, Essex North, said that it was his impression that Miss Tracy had endeavored unsuccessfully to make contact with the district societies concerned. He expressed his belief that, in turning down the recommendation of the Committee on Public Health, the Council was sticking too closely to the proprieties of the situation. If Miss Tracy's request, he continued, were given serious thought by the district societies concerned, it would not be necessary for the Society to take action. Finally he expressed his opinion that the Society should not turn down a request to use its good offices in a matter that was of public interest.

Dr Alexander J A Campbell, Suffolk, said that he spoke under instruction from the Suffolk District Medical Society, whose opinion was unanimous that the Massachusetts Medical Society has the responsibility of co-operating with the Massachusetts Nursing Council in its program to develop the best possible form of nursing organization in Massachusetts and that the Society should take whatever appropriate action might be deemed necessary, because the Massachusetts Nursing Council as such is not active and because its work is largely being carried on by the Greater Boston Nursing Council.

He moved as an amendment to the amendment that the President appoint a committee to confer with the chairman of the Greater Boston Nursing Council for the purpose of determining ways and means by which the common interests of these closely allied professions might be better developed.

Dr Peirce H Leavitt, Plymouth, spoke for the adoption of the recommendations of the Executive Committee.

The President elected first to put the recommendation offered by the Committee on Public Health. This was lost by vote of the Council. The President then put the recommendations offered by the Executive Committee. These recommendations were adopted by vote of the Council.

This matter having thus been disposed of, the recommendation offered by the representative from Suffolk was not put to a vote.

Committee on Society Headquarters—Dr Frank R Ober, Suffolk, chairman.

This report, which was offered by the chairman, is as follows:

The Committee on Society Headquarters still continues to give serious study to the possible expansion of the Society Headquarters.

It has, however, nothing definite to report in the matter at this time.

The chairman moved the acceptance of this report. The motion was seconded, and it was so ordered by vote of the Council.

Committee on Physical Medicine — Dr Arthur L Watkins, Middlesex South, chairman

This report, which is as follows, was submitted by the chairman:

As no new or special problems have been laid before this committee, its report is purely to inform the Society on developments in the field of physical medicine thought to be of interest. An outstanding event has been a more generally accepted recognition of the needs for expansion of knowledge in physical medicine and of more widespread utilization of measures already known to be effective in aiding recovery from disease and injury and occasionally in prevention and diagnosis. The gift of Bernard M. Baruch to foster research and teaching is noteworthy. At the Harvard Medical School a fellowship program was inaugurated one year ago to train promising men to become investigators and teachers. These fellowships extend over a three-year period including time for fundamental research. A three months' course which is offered at the Massachusetts Institute of Technology in biophysics aimed to instruct physicians in methods of instrumentation applicable to medical problems is another valuable Baruch project. It is expected that physical medicine will play an increasingly important role, particularly in problems of rehabilitation. All physicians are accordingly urged to acquaint themselves with the therapeutic possibilities of physical and occupational therapy. An annual progress report on research in physical medicine has been prepared for publication in the *New England Journal of Medicine* in order that the general practitioner may become familiar with the scientific background of physical medicine today.

The chairman moved the acceptance of the report. This motion was seconded, and it was so ordered by vote of the Council.

Committee on Public Relations — Dr Albert A Hornor, Suffolk, secretary

This report, which is as follows, was submitted by Dr Hornor:

The Secretary of the Committee on Public Relations has notified the secretaries of the district medical societies of the approval of the committee of the action taken by a group of physicians in Lowell, independent of the Massachusetts Medical Society, to educate their local public through advertising. Included in the letter were examples of the advertisements that had been put out in Lowell and in Newton and other groups. No action on this matter is requested.

The Committee on Public Relations has reviewed the report of the Special Committee Appointed to Confer with General Hawley anent the medical care of veterans in private hospitals and in the veterans' homes. The committee has likewise reviewed a schedule of fees intended to cover the charges for such medical care. The committee approved the report and the fee schedule.

The Committee on Public Relations approved the project of enrolling members of the Massachusetts Medical Society in the Blue Cross and recommends to the Council that this be effected in the manner considered most efficient by the secretary of the Massachusetts Medical Society and by the officials of Blue Cross.

The Committee on Public Relations is unwilling to take a stand on the question as to enrollment of the members of the Society in the Blue Shield. The question which is involved here is whether or not enrollment of members in

the Blue Shield might or might not affect the tradition whereby one doctor supplied medical care to another or to the other's family, without charge. The Committee on Public Relations has requested that Dr Milton Quinn, chairman of the subcommittee that has investigated this question, present the problem to the Council.

In discussing this report, Dr Hornor said it contained a recommendation that the Council approve of the enrollment of the members of the Massachusetts Medical Society in the Blue Cross in such a manner as is considered most efficient by the secretary of the Society and the officials of the Blue Cross. He moved the adoption of this recommendation. The motion was seconded, and it was so ordered by vote of the Council.

Dr Hornor then stated that the matter of enrolling the members of the Society in the Blue Shield had been discussed by the committee, which offered no recommendation in this regard.

He called on Dr Milton J Quinn, Middlesex East, to present the argument for such enrollment. Dr. Quinn spoke as follows:

The members of the Committee on Public Relations declined to take definite action in the problem of the enrollment in the Blue Shield on the ground that it involved a very important principle in the practice of medicine, namely, the question of cash payment from one physician to another for services rendered.

Gratuitous care by one physician to another and his family has been a sacred principle of our profession throughout the centuries. It will continue thus in many quarters well into the foreseeable future. There are good reasons why strict adherence to this worthy principle has not always been practiced. A sort of a barter plan grew in popularity. A pair of tonsils is swapped for a beautiful Gladstone bag. A broken leg for a savings bond, which is approaching more closely a cash exchange and so on.

Some physicians and their families are so insured that in the event of accident or illness the attending physician is requested to send a bill for his services so that the insured may receive certain allowances. With communication and transport as they are today, it means overburdening more people in our profession with the care of doctors and their families. Some of the load is carried by all.

The interested committees of this Council have recently had under consideration a fee schedule applicable to war veterans and their dependents. This will include, I am sure, some doctors and their families. Shall we accept such fees? Shall we accept the fees offered by the Blue Shield? The problem now presented to the Council is whether or not it will approve the enrollment of the members of the Massachusetts Medical Society in the Blue Shield in a manner as suggested in the Blue Cross enrollment mentioned by Dr Hornor.

At this point in the meeting, the President declared a short recess so as to afford those in the rear of the room to come forward, where ample seating space was available.

When the Council reconvened, the President asked the Secretary to state the views of the Executive Committee on this subject. The Secretary spoke as follows:

In the discussion attending this subject before the Executive Committee, Dr Milton Quinn was heard. He expressed it as his belief that many members of the Society were overburdened by the care of other physicians and their families. He saw no reason why individual members of the Society might not join the Blue Shield, if they so desired. The question at issue, as he defined it, was whether or not the Massachusetts Medical Society should endorse their joining.

In connection with that subject, Section 2, Article II, of the "Principles of Medical Ethics" of the American Medical Association was read into the record. This section reads as follows:

When a physician from a distance is called on to advise another physician or one of his family dependents, and the physician to whom the service is rendered is in easy financial circumstances, a compensation that will at least meet the traveling expenses of the visiting physician should be proffered. When such a service requires an absence from the accustomed field of professional work of the visitor that might reasonably be expected to entail a pecuniary loss, such loss should, in part at least, be provided for in the compensation offered.

It was pointed out that at least inferentially, except under the circumstances outlined, this section indicates that it is not considered good medical ethics for one physician to charge another for services rendered.

The Executive Committee likewise offers no recommendation regarding this matter.

The President stated that two committees had studied this matter and had apparently arrived at no conclusion.

Dr. Ralph R. Stratton, Middlesex East, chairman of the Committee on Ethics and Discipline, was recognized by the chair. Dr. Stratton spoke as follows:

My feeling is strong that the article of the ethics of the American Medical Association in regard to this matter should stand. I believe that any man who is asked by a neighboring or fellow physician to take care of his family should feel complimented and be glad to attend that family for nothing, except that his expenses might be paid if the person receiving the service is in easy circumstances. I am heartily opposed to joining the Blue Shield in order that we might be paid for taking care of our own in their need.

Dr. Stratton's remarks were greeted with applause.

Dr. Charles J. E. Kickham, Norfolk, moved that the subject under discussion be laid on the table. This motion was seconded, and it was so ordered by vote of the Council.

Dr. Hornor moved that the report of the Committee on Public Relations, as a whole, excluding the part referring to enrollment in the Blue Shield, be adopted. This motion was seconded, and it was so ordered by vote of the Council.

By permission of the President, Dr. Daniel J. Ellison, Middlesex North, chairman of the Subcommittee Appointed to Confer with the Massachusetts Industrial Accident Board, offered the following supplement to the report of the Committee on Public Relations:

Some months ago the Norfolk District Medical Society brought in a resolution which called for a review of the fees allowed by the Massachusetts Industrial Accident Board. The matter was referred to the subcommittee, consisting of Dr. David D. Scannell, Dr. Gordon M. Morrison and myself. The work of this subcommittee in this respect was finished yesterday morning.

Henceforth a physician examining a workman who has developed a hernia as the result of his occupation is allowed a fee of \$3.00 for an examination looking toward the establishment of this as a fact, when such a physician does not perform an operation. The surgeon operating on such an individual is allowed a fee of \$75.00 for single and \$100.00 for a double hernia. The operating surgeon is allowed no examination fee.

House calls to individuals injured in industry will be allowed at the rate of \$4.00 per call. Hospital calls under these same circumstances will be at the rate of \$3.00 per call. Office calls will be at the rate of \$2.50 per call.

These represent substantial increases in the fees allowed for the medical care of industrial accident cases.

We are very appreciative of the efforts of those groups concerned with these successful negotiations. Notable among those groups were the Massachusetts Industrial Accident Board, Mrs. Emma S. Tousant, chairman, the Medical Advisory Committee of the Industrial Accident Board, Dr. Cadis Phipps, chairman, and the subcommittee of the Committee on Public Relations.

Dr. Ellison moved the acceptance of the supplementary report. This motion was seconded, and it was so ordered by vote of the Council. (Dr. Ellison left the platform amid applause.)

Committee on Postwar Planning — Dr. Howard F. Root, Suffolk, chairman.

Dr. Root submitted the report (Appendix No. 7) as published in the circular of advance information.

It was stated that the Commonwealth, for purposes of postgraduate education, had been divided into seven districts, all of which had at least two sets of courses except District No. 1, in which courses were at the moment in preparation. In District No. 7, which includes the Greater Boston area, bi-weekly postgraduate programs were held from February 18 to May 15, 1946. Over a thousand physicians were registered for these courses. The average attendance at each exercise was over 500.

The report said that the Subcommittee on Veterans Affairs had been set up and a questionnaire distributed at the bi-weekly exercises mentioned above. The replies to this questionnaire indicated the need of office space, telephone listing and the enlargement of the activities of the Information Bureau at 8 Fenway.

The report decried the failure of the district societies to fill out completely the questionnaire sent out by the American Medical Association. This failure made it impossible for the Information Bureau to give advice regarding opportunities for practice in various parts of the Commonwealth.

Finally, the report mentioned a conference that was held with the Massachusetts Hospital Association concerning the provision of hospital appointments for veterans.

Supplementing the report, Dr. Root said that during the period of the annual meeting a questionnaire would be found at the registration desk, the purpose of which was to obtain information from the physicians in attendance, veterans and otherwise, regarding how the Committee on Postwar Planning might better serve the interests of the returning veteran doctor.

He moved the acceptance of the report. This motion was seconded, and it was so ordered by vote of the Council.

Committee on Legislation — Dr. David L. Belding, Norfolk South, chairman.

Dr. Belding submitted the report (Appendix No. 8) as published in the pamphlet of advance information. The report was debated in executive session.

Dr Belding moved the adoption of the report and their recommendations contained in it. This motion was seconded.

The President called on the Secretary for such comment as the Executive Committee wished to make regarding this report. The Secretary stated that the Executive Committee, in approving of the report and the recommendations contained in it, applauded the wisdom that it displayed.

The motion was passed by vote of the Council (Dr Belding left the platform amid loud and prolonged applause).

Massachusetts Delegates to the Council of the New England State Medical Societies

This report (Appendix No 9) was offered by the Secretary as it appeared in the pamphlet of advance information. He moved its acceptance. This motion was seconded, and it was so ordered by vote of the Council.

The Secretary said that the Executive Committee recommended, subject to the approval of the Committee on Finance, that the Council appropriate the sum of \$100.00 for the use of the New England Council during the ensuing year. In reference to this recommendation he stated that each medical society in the Council would appropriate a like amount. He moved the adoption of the recommendation. The motion was seconded, and it was so ordered by vote of the Council.

Committee on Postwar Loan Fund—Dr George Leonard Schadt, Hampden, chairman

This report, which is as follows, was offered by the chairman:

This report of the Committee on Postwar Loan Fund is informational only.

This fund was activated by the Council at its meeting in October, 1945, and since that date eleven loans have been made, each for five hundred dollars. In addition, there are three loans pending.

Forty-four requests for information concerning the loan have been received by the committee.

Dr Schadt moved the acceptance of the report. This motion was seconded, and it was so ordered by vote of the Council.

Report of the Massachusetts Representative to the House of Delegates of the American Medical Association

This report (Appendix No 10), as published in the pamphlet of advance information, was submitted by Dr David D Scannell, Norfolk. He moved its acceptance. This motion was seconded, and it was so ordered by vote of the Council.

Committee Appointed to Make Recommendations for Directors of the Blue Shield—Dr Leland S McKittrick, Suffolk, chairman

In the absence of Dr McKittrick, the Secretary submitted the following report:

The Committee to Make Recommendations for Directors of the Blue Shield submits the names of the following men:

To hold office until 1947:

Mr Philip Morgan — reappointment
Dr Norman A Welch — reappointment
Dr Arthur W Allen — reappointment
Mr J H Humphreys — reappointment
Mr Roswell Phelps — reappointment

To hold office until 1948:

Dr Eugene Walker, superintendent Springfield Hospital, Springfield, to replace Mr Oliver G Pratt (resigned)
Mr Thomas G Brown — reappointment
Dr Elmer S Bagnall — reappointment
Mr Ernest A Johnson — reappointment
Mr Daniel J Boyle — reappointment

To hold office until 1949:

Mr Hugh Nawn, president, Hugh Nawn Incorporated Boston, to replace Mr Thomas Dignan (term expired)
Mr Joseph K Miliken, Jr, superintendent, Mr Hope Finishing Company, Dighton, to replace Mr P A O'Connell (term expired)
Dr Samuel A Robins — reappointment
Dr James C McCann — reappointment
Mr Harold B Leland — reappointment

The Secretary moved the acceptance of this report. This motion was seconded, and it was so ordered by vote of the Council.

Committee Appointed to Confer with the Massachusetts Hospital Association—Dr Walter G Phippen, Essex South, chairman

The report, which is as follows, was presented by the chairman:

This committee was instructed to consult with the Massachusetts Hospital Association as to activation of the Galluppe Plan to determine the position graduates of substandard schools might take on hospital staffs.

In accordance with this vote the chairman wrote to the president of the Massachusetts Hospital Association and received the following reply which is self-explanatory:

March 7 1946

Dr Walter G Phippen
31 Chestnut Street
Salem Massachusetts

Dear Doctor Phippen:

The recommendations of the Council of the Massachusetts Medical Society bearing on graduates of substandard schools, which you sent me recently, were presented to the trustees of the Massachusetts Hospital Association. On that same occasion Dr Galluppe sat in with the trustees giving his endorsement to the recommendations and outlined his plan for making these recommendations effective in the Waltham Hospital.

The trustees of the Massachusetts Hospital Association were entirely in sympathy with this movement to provide opportunities in hospitals for these graduates of substandard schools and agreed to co-operate in the movement.

The manner of doing so is to be something like this:

To inform the member hospitals of the Association by letter that the trustees of the Massachusetts Hospital Association believe it desirable that graduates of substandard schools be given opportunities in hospitals under suitable regulation.

To advise the member hospitals that we endorse the recommendations of the Massachusetts Medical Society looking to this end.

That we send each hospital of the Association a copy of these recommendations of the Council.

I believe that the secretary of the Association is to be furnished with a supply of these printed recommendations, a copy of which you sent me and which I left with the secretary. These are to be included in a letter which goes to the membership.

Having thus agreed with your committee and the Council of the Massachusetts Medical Society and moving in this way to give effect to the recommendations it seems to me it should about meet the needs of the present.

In connection with that subject, Section 2, Article II, of the "Principles of Medical Ethics" of the American Medical Association was read into the record. This section reads as follows:

When a physician from a distance is called on to advise another physician or one of his family dependents, and the physician to whom the service is rendered is in easy financial circumstances, a compensation that will at least meet the traveling expenses of the visiting physician should be proffered. When such a service requires an absence from the accustomed field of professional work of the visitor that might reasonably be expected to entail a pecuniary loss, such loss should, in part at least, be provided for in the compensation offered.

It was pointed out that at least inferentially, except under the circumstances outlined, this section indicates that it is not considered good medical ethics for one physician to charge another for services rendered.

The Executive Committee likewise offers no recommendation regarding this matter.

The President stated that two committees had studied this matter and had apparently arrived at no conclusion.

Dr. Ralph R. Stratton, Middlesex East, chairman of the Committee on Ethics and Discipline, was recognized by the chair. Dr. Stratton spoke as follows:

My feeling is strong that the article of the ethics of the American Medical Association in regard to this matter should stand. I believe that any man who is asked by a neighboring or fellow physician to take care of his family should feel complimented and be glad to attend that family for nothing, except that his expenses might be paid if the person receiving the service is in easy circumstances. I am heartily opposed to joining the Blue Shield in order that we might be paid for taking care of our own in their need.

Dr. Stratton's remarks were greeted with applause.

Dr. Charles J. E. Kickham, Norfolk, moved that the subject under discussion be laid on the table. This motion was seconded, and it was so ordered by vote of the Council.

Dr. Hornor moved that the report of the Committee on Public Relations, as a whole, excluding the part referring to enrollment in the Blue Shield, be adopted. This motion was seconded, and it was so ordered by vote of the Council.

By permission of the President, Dr. Daniel J. Ellison, Middlesex North, chairman of the Subcommittee Appointed to Confer with the Massachusetts Industrial Accident Board, offered the following supplement to the report of the Committee on Public Relations:

Some months ago the Norfolk District Medical Society brought in a resolution which called for a review of the fees allowed by the Massachusetts Industrial Accident Board. The matter was referred to the subcommittee, consisting of Dr. David D. Scannell, Dr. Gordon M. Morrison and myself. The work of this subcommittee in this respect was finished yesterday morning.

Henceforth a physician examining a workman who has developed a hernia as the result of his occupation is allowed a fee of \$3.00 for an examination looking toward the establishment of this as a fact, when such a physician does not perform an operation. The surgeon operating on such an individual is allowed a fee of \$75.00 for single and \$100.00 for a double hernia. The operating surgeon is allowed no examination fee.

House calls to individuals injured in industry will be allowed at the rate of \$4.00 per call. Hospital calls under these same circumstances will be at the rate of \$3.00 per call. Office calls will be at the rate of \$2.50 per call.

These represent substantial increases in the fees allowed for the medical care of industrial accident cases.

We are very appreciative of the efforts of those groups concerned with these successful negotiations. ^{Noted} among those groups were the Massachusetts Industrial Accident Board, Mrs. Emma S. Tousant, chairman, the Medical Advisory Committee of the Industrial Accident Board, Dr. Cadis Phipps, chairman, and the subcommittee of the Committee on Public Relations.

Dr. Ellison moved the acceptance of the supplementary report. This motion was seconded, and it was so ordered by vote of the Council. (Dr. Ellison left the platform amid applause.)

Committee on Postwar Planning — Dr. Howard F. Root, Suffolk, chairman.

Dr. Root submitted the report (Appendix No. 7) as published in the circular of advance information.

It was stated that the Commonwealth, for purposes of postgraduate education, had been divided into seven districts, all of which had at least two sets of courses except District No. 1, in which courses were at the moment in preparation. In District No. 7, which includes the Greater Boston area, bi-weekly postgraduate programs were held from February 18 to May 15, 1946. Over a thousand physicians were registered for these courses. The average attendance at each exercise was over 500.

The report said that the Subcommittee on Veterans Affairs had been set up and a questionnaire distributed at the bi-weekly exercises mentioned above. The replies to this questionnaire indicated the need of office space, telephone listing and the enlargement of the activities of the Information Bureau at 8 Fenway.

The report decried the failure of the district societies to fill out completely the questionnaire sent out by the American Medical Association. This failure made it impossible for the Information Bureau to give advice regarding opportunities for practice in various parts of the Commonwealth.

Finally, the report mentioned a conference that was held with the Massachusetts Hospital Association concerning the provision of hospital appointments for veterans.

Supplementing the report, Dr. Root said that during the period of the annual meeting a questionnaire would be found at the registration desk, the purpose of which was to obtain information from the physicians in attendance, veterans and otherwise, regarding how the Committee on Postwar Planning might better serve the interests of the returning veteran doctor.

He moved the acceptance of the report. This motion was seconded, and it was so ordered by vote of the Council.

Committee on Legislation — Dr. David L. Belding, Norfolk South, chairman.

Dr. Belding submitted the report (Appendix No. 8) as published in the pamphlet of advance information. The report was debated in executive session.

talked very plainly. We told them that it was a matter of education, that we believed that they were not so well educated as they might have been, and they admitted it. I have never found one yet that did not regret that he had gone to a substandard medical school. They said that they were perfectly willing to do their share in improving themselves in the care of their patients. We started by inviting them to our staff meetings, which are purely educational, and to our clinical pathological conferences, which likewise are purely educational. They all came regularly, every one of them. Our staff attendance increased. It was better than we ever expected it would be. Enthusiasm about the staff meetings increased. The members of the active and consulting staffs were put on the spot clearly to show how good they were to these men who had not had so good an opportunity as they had had. I am sure that our hospital has increased its efficiency in the medical care of the citizens of Waltham and its educational value to all the physicians practicing in that community. I know of several lives that have already been saved because these men were able to get critically ill patients into a good hospital immediately. One of our rules was that every one of these men should make application for membership in the Massachusetts Medical Society at the earliest possible moment. Some of them are not eligible because they have not been licensed five years in this state, and those men of course are the ones who need help most. The men who have been practicing for five, ten or fifteen years perhaps do not need so much help as those who are just out of one of these inferior schools. We have taken them all in and have carefully supervised their work.

Give them all an equal chance and then, if you find that they are not satisfactory as members of your supervised courtesy staff — and that is what we call them — you can drop them, that is your privilege. But I do not believe that you will. The tendency will be to improve the teaching all the time, and they will improve all the time and the care of their patients will steadily improve, and as the result you will have a community receiving better hospital care. You will also have a community of effort in the raising of funds. You can imagine in Waltham, for instance, with twelve doctors not allowed to use the hospital and with perhaps ten or twelve thousand of the population, since they are the patients of these doctors, not being able to use our hospital, how disunited we became when attempting to raise funds for the hospital. This past fall, however, the Waltham Hospital attempted to raise \$100,000 to increase the efficiency of the institution, we raised it immediately with a united public effort, and I am sure that it was at least in part due to the operation of this plan, which everybody in the community greets with great pleasure.

I was certain from the beginning that the American College of Surgeons and the Council on Medical Education and Hospitals of the American Medical Association would not disagree with our plan. How could they? They could not disagree with something that was going to benefit the public. And that is the argument that we used in the Legislature in all the legislative bills this year. We have proved to the legislators that we are not after anything — we are simply out to give the people of this state the best possible medical care.

(Dr. Gallupe's remarks were greeted with applause.)

Dr. Nathaniel W. Faxon, Suffolk, in addressing the Council on this subject, spoke as follows:

This is in the nature of a testimonial to Dr. Gallupe's plan and Dr. Phippen's report, and partly in answer to Dr. Schadt's question.

Three years ago a young man from the South Shore who was a graduate of the Middlesex School applied for a residency at the Massachusetts General Hospital. He was investigated very carefully, and it was felt that he had the right stuff in him. He was given an appointment as a resident in anesthesia. He served for two years. He demonstrated his ability and his willingness to work hard and to learn. He is now a member of the paid anesthesia staff at the Massachusetts General Hospital, and we are very glad to have him. This is a direct successful application of the principle. I do not know whether he is a member

of the Massachusetts Medical Society or not. I do not know whether he has been out of Middlesex long enough to be a member. But I do know that he has made good, and I have every confidence that he will continue to be a credit to the hospital and to the medical profession.

(Dr. Faxon's remarks were also applauded.)

The motion to accept the report was adopted by vote of the Council.

Committee to Confer With the Massachusetts Farm Bureau Federation — Dr. Joseph C. Merriam, Middlesex South, chairman.

This report, which is as follows, was presented by the chairman:

This committee was appointed on October 17, 1945. It communicated, forthwith through the chairman, with the Massachusetts Farm Bureau Federation, and received an answer to the effect that there were no immediate problems of the Bureau regarding rural medicine, but that there undoubtedly would arise from time to time matters about which they would wish to confer. The Bureau was assured of this committee's interest and willingness to give them any service they could.

Several communications were received from the committee on Rural Medicine of the American Medical Association, from the American Farm Bureau Federation and from certain midwestern and southern state associations. This literature was carefully studied.

It is the opinion of this committee that whereas there is great need for improvement in rural medical facilities in certain areas of the country, Massachusetts does not present these problems to any great degree. The committee, however, feels that Massachusetts should support the national work and be ready to help its own state farm agencies when and if it is requested by them to do so.

Dr. Merriam moved the acceptance of the report. This motion was seconded, and it was so ordered by vote of the Council.

Representative of the Massachusetts Medical Society on the Massachusetts Committee for Nurses Procurement and Assignment Service — Dr. Dwight O'Hara, Middlesex South.

Dr. O'Hara reported as follows:

The Massachusetts Committee for Nurses Procurement and Assignment Service of the War Manpower Commission, was established by Congressional action in June of 1943. The Massachusetts Medical Society was represented in its deliberations from May, 1944, until it was dissolved on December 31, 1945. Up to September 1, 1945, the Service had classified 9812 nurses, most of whom were of military age. In all 4867 nurses were assigned from Massachusetts, 1146 of them being assigned between January 1 and August 1, 1945. The personnel of the state committee was as follows: Katharine E. Peirce, Mary E. G. Bliss and Hilga Nelson, chairmen; Mrs. Lloyd D. Brace, Dorothy J. Carter, Nathaniel W. Faxon, M.D. (representing the Massachusetts Hospital Association), Mrs. Bessie P. Hanson, Blanche A. Harman, Katherine F. McCahe, Dwight O'Hara, M.D. (representing the Massachusetts Medical Society), Helen O. Potter and Eva S. Waldron. This committee handled a difficult assignment in a creditable manner, serving without compensation and in complete co-operation with all other wartime needs. It is a pleasure to report to the Council the effective work thus done by the nurses of the Commonwealth.

The President asked the Secretary for such comment as the Executive Committee wished to make regarding the report. The Secretary replied that the Executive Committee recommended that this representation be abolished.

It may be desirable at some time in the near future to check up and see what is being done by the several hospitals of the Association and a meeting at that time may be profitable.

Should, however, you desire an earlier meeting I feel sure it can be arranged though it will be in the next administration for my term ends this month.

Sincerely yours,

(Signed) GEORGE A. MACIVER, M.D. President
Massachusetts Hospital Association

The committee will give further consideration as to what should be done to acquaint hospital staffs with the action of the Council.

In discussing this report, Dr Phippen referred to the last sentence in the report proper. He said that, in furtherance of the promise contained in this sentence, the committee had sent a letter to the staffs of all the hospitals in the Commonwealth stating the following:

The enclosed plan was adopted by the Council of the Massachusetts Medical Society on February 6, 1946, and was referred to the Committee to Meet with the Massachusetts Hospital Association. The trustees of the Massachusetts Hospital Association have unanimously agreed to co-operate, and its constituent members have been so informed. The committee therefore requests that you present this plan to your staff and urge its adoption.

Since that time, Dr Phippen continued, the committee had received the following letter from the American College of Surgeons:

AMERICAN COLLEGE OF SURGEONS
40 East Erie Street
Chicago 11, Illinois

Dr. Walter G. Phippen, Chairman
Committee to Meet With the
Massachusetts Hospital Association
31 Chestnut Street
Salem, Massachusetts

April 12, 1946

My dear Doctor Phippen:

Acknowledgment is made of your letter of March 29 relative to the actions and recommendations of the Massachusetts Medical Society and the Massachusetts Hospital Association on graduates of nonapproved medical schools.

The acceptance of interns and residents who are graduates of nonapproved medical schools is the responsibility of the governing body of the hospital in this the American College of Surgeons does not advise or interfere. However, as the American Medical Association approves hospitals for the training of interns, it is advisable that this matter be taken up with that organization in order that there will be no misunderstanding on this subject.

The great trouble with graduates from nonapproved medical schools is the fact that they lack the fundamental education for the practice of medicine and in most instances take the minimum hospital training following graduation, and this usually to a hospital not approved for internships and residencies. We have found case after case in our surveys of hospitals where graduates of these schools, after one year internship in unrecognized hospitals, were attempting to do everything in surgery, obstetrics and highly specialized fields of medicine.

As to the appointment of graduates of nonapproved medical schools to the medical staff of the hospital this is likewise the prerogative of the governing body of the hospital, in co-operation with the proper committee of the active medical staff. Neither the American College of Surgeons nor any other organization may usurp this authority. The American College of Surgeons through its hospital standardization program requires that the professional work of these physicians be under adequate supervision and control and that the privileges extended to them in the hospital be consistent with their qualifications. In order that the welfare of the individual patient will be assured. When these principles of hospital standardization are adequately heeded there is no hazard to the rating of the hospital from this aspect.

Trusting that the foregoing will be of value to you and assuring you of our continued interest and co-operation I am

Very sincerely yours

(Signed) MALCOLM T. MACEachern, M.D.
Associate Director

Dr Phippen also read into the record the following letter, received from the Council on Medical Education and Hospitals of the American Medical Association:

AMERICAN MEDICAL ASSOCIATION
COUNCIL ON MEDICAL EDUCATION AND HOSPITALS
535 North Dearborn Street, Chicago 10

Office of the Secretary
April 24 1946

Dr. Walter G. Phippen
31 Chestnut Street
Salem, Mass.

Dear Doctor Phippen:

At the request of Dr. Victor Johnson, secretary of the Council, I wish to acknowledge your letter of March 29.

The plan which you enclosed would seem to be a logical method of supervising work of registered physicians who do not yet hold hospital appointments. At the same time, it will enable the medical staff to determine the professional competence of individual physicians particularly in relation to subsequent staff appointments and assignment of hospital privileges in various fields of practice. The method which your committee has proposed is similar to many respects to the accompanying statement which has been forwarded to several hospitals in the New England area and also to the Massachusetts Medical Society.

Sincerely yours,

(Signed) F. H. ARZSTAD, M.D.

* * *

The Council on Medical Education and Hospitals is interested in guarding against hospital staff appointments to physicians lacking in professional competence. In its standards, therefore, it has indicated that appointments should be limited to graduates of approved medical schools who have satisfactory qualifications as to training, licensure and ethical standing.

If the graduates of other medical schools wish to obtain the privilege of hospital appointment, their qualifications should likewise be evaluated on the basis of credentials, training and experience in medical practice. It would seem essential, therefore, that such applicants should have a sufficient period of service in the community to enable the medical staff to determine their professional competence. Their applications should then be considered on the basis of individual merit as in the case of other physicians. In this connection, it is necessary to keep in mind that the primary function of the hospital and its staff is to safeguard the care and welfare of the sick.

Dr Phippen moved the adoption of the report. This motion was seconded.

The Secretary suggested that it might be well to send copies of the letters received from the American Medical Association and the American College of Surgeons to each hospital in Massachusetts because of the assurance given that the status of the hospital participating in the plan would not be unfavorably affected by such participation. This suggestion was referred by the President to the committee.

Dr Schadt asked if graduates of unapproved schools who are members of the Massachusetts Medical Society are to be treated under this plan as graduates of the same type of school who are not members of the Society. He pointed out that the former group have already had a five-year probationary period.

Dr Phippen stated that this was a question that must be answered by each hospital dealing with the individual doctor.

Dr H. Quimby Gallupe, Middlesex South, said that he had promised to put this plan into operation in the Waltham Hospital. He continued as follows:

We have in Waltham twelve physicians registered and practicing who are graduates of substandard schools, and the Executive Committee of the staff of the Waltham Hospital believed that it would be very difficult to differentiate one man from another, in other words that it would be almost impossible to pick out of that group men who were more fitted than others to work with the hospital on this plan. We had the plan adopted by the staff of the hospital and then accepted by the Trustees. The responsibility for the working of the plan was left in the hands of the staff.

Through the Executive Committee we invited these twelve men to come to the hospital to a meeting, where the plan was explained to them, we had written copies of rules that would govern their activities in the hospital and we

tion, and that he be appointed by the Council on proposal by a committee of seven to be named by the President.

The only specific duty, then, of this committee is to select and propose the name of a candidate for this position.

The committee felt that the selection of the right man required a definition of his duties far more precise than is given in the vote of the Council, to the end that his qualities and attainments should be adapted to these duties. They therefore communicated with all the state medical societies and the American Medical Association in order to learn of and profit by their experience, and also asked the officers of our district societies to suggest candidates from among their members. This is not the time to summarize and evaluate the many issues and problems thus brought to light. The committee feels that much of the work of the new director must at first be of an exploratory and tentative character and that its final emphasis and value cannot be predicted. Much will depend on the particular talents which he may bring to his office. It believes that ideally the incumbent should be a physician, a member of the Society, experienced in practice and in early middle life, so that before him may stretch a long career of usefulness, which will steadily increase with his experience. Such a man must of course be on a full-time basis, and receive a salary sufficient to enable him to relinquish the income from a successful practice. His appointment should be terminated on his reaching a prescribed age, as in the case of academic or teaching appointments.

The committee has failed thus far to discover a suitable candidate with all these qualifications. They agree that the selection of the candidate is a matter of paramount importance and have preferred to proceed with caution rather than to run the risk through haste of committing a grave error. This report, therefore, is one of progress and contains no recommendation.

Dr Bagnall moved the acceptance of the report. This motion was seconded, and it was so ordered by vote of the Council.

Other Committees

The President stated that no reports had been received from the standing committees on Ethics and Discipline and Industrial Health, or from the special committees on Council Rules, Maternal Welfare, Medical Advisory to Regional OPA and Rehabilitation. Each of these committees had reported at least once during the last year, in accordance with Section 1, Chapter VII of the By-laws. No report had been received from the Committee on Expert Testimony during the preceding year, but this committee received special consideration at the Council meeting on February 6. The question was on the acceptance of a report of no report from each of these several committees.

A motion to this effect was made, seconded and carried.

Committee on Nominations — Dr Ralph R. Stratton, Middlesex East, chairman

Dr Stratton reported as follows

The Committee on Nominations of the Massachusetts Medical Society met on April 3, 1946, at 8 Fenway, Boston, and submitted the following list of officers for the year 1946-1947

President DWIGHT O'HARA, Middlesex South
President-Elect EDWARD P. BAGG, Hampden
Vice-President ISSAC S. F. DODD, Berkshire
Secretary MICHAEL A. TIGHE, Middlesex North
Treasurer ELIOT HUBBARD, JR., Middlesex South
Assistant Treasurer NORMAN A. WELCH, Norfolk
Orator LELAND S. MCKITTRICK, Suffolk

The President asked for nominations from the floor. There were none. A motion was made to close all nominations. The motion was seconded, and it was so ordered by vote of the Council.

Dr Stratton moved that the Secretary be instructed to cast one ballot for the list of officers as submitted by the Committee on Nominations. This motion was seconded, and it was so ordered by vote of the Council.

The Secretary stated that he had complied with this directive, and the President announced that the above mentioned officers were elected.

The President then introduced Dr Dwight O'Hara, president of the Massachusetts Medical Society for the year 1946-1947, who addressed the Council as follows

My professional life has been blessed with many opportunities and many honors. The opportunities I am sure I have not risen to, and the honors I am sure I have not deserved, but this is, I am also most sure, the greatest opportunity and the greatest honor that has been bestowed upon me, and I shall try to do all that I possibly can to be deserving of it. Thank you.

Dr Stratton was appointed by the President to escort Dr Edward P. Bagg, Hampden, president-elect, to the platform. On being introduced to the Council, Dr Bagg spoke as follows

Gentlemen, now you know what the trouble is with your nominating councilors. They have held office too long, and their judgment is uncertain. I will do the best I can, but I must say, if the rules become mixed up with poetic license, it is your fault, and not mine. I was not consulted, gentlemen.

At this point in the meeting the President spoke as follows

Before calling on the President-Elect to fulfill his duty, the chair desires to make a final gesture. He wishes to remind the Council of an interesting bit of history.

The by-laws adopted in April, 1782, state that the Librarian shall have in his custody and charge all books belonging to the Society and shall cause each to be marked on the inside cover with the arms of the Society. On June 7, 1821, the Librarian was further directed to cause the name of the donor to be inserted in each volume.

The chair suggests that each incoming presiding officer of the Council should make his first official appearance with some appropriate ceremony. In this connection there are, he thinks, two insignia of the Society that should be passed in the presence of the Council from one presiding officer to the next.

The first comprises the annual proceedings of the Council for the previous ten years. Their careful study is required by all chairmen.

Each of these eleven volumes before you has been duly marked on the inside cover with the Society's bookplate prepared in 1782, and in accordance with the Council's wish of 1821, has the name of the donor inserted — the President who presided at the first meeting of the Council in that calendar year after his election.

The second is the chairman's copy of *Robert's Rules of Order*, also duly marked with the Society's bookplate. Without this well known guide, no chairman can hope to fulfill his specified duty of presiding at the meetings of even so considerate and tolerant a body as the Council.

Mr Secretary, as retiring chairman of the Council, I now turn back to your hands the volume of the proceedings of the Council for 1935. Dr O'Hara, these insignia are now yours to guard during the one hundred and sixty-sixth year of the Society's life.

Dr O'Hara moved the acceptance of the report and the adoption of the recommendation of the Executive Committee. This motion was seconded, and it was so ordered by vote of the Council.

Representative to the Mental Health for Victory Organization — Dr Abraham Myerson, Norfolk

In the absence of Dr Myerson, the Secretary read the following report, which had been submitted by Dr Myerson:

I think that the Council should be informed that the Mental Health for Victory Organization was "as idle as a painted ship upon a painted ocean." I went to one meeting. No other meetings were called, so far as I know, and nobody did anything at all about it. In fact, nothing could have been done.

I am sorry that the report has to be as futile as it is, but that is the way things went, and I am giving you a candid report.

The Secretary moved the acceptance of the report. This motion was seconded.

The President asked the Secretary for such comment as the Executive Committee might wish to make regarding this report. The Secretary replied that the Executive Committee recommended that this representation be abolished.

The question, as put by the President, was that the report be accepted and the recommendation of the Executive Committee be adopted. It was so ordered by vote of the Council.

Representative to the Legislative Committee of the Massachusetts Central Health Council — Dr William E Browne, Suffolk

The report, as submitted by the chairman, is as follows:

Your representative has attended one meeting of the Legislative Committee of the Massachusetts Central Health Council during the past year. He believes that the Society should continue to have representation on this committee. The Massachusetts Central Health Council has great potentialities and deserves co-operation from the Society.

Dr Browne moved the acceptance of the report. The motion was seconded, and it was so ordered by vote of the Council.

Committee on Postgraduate Assembly — Dr Leroy E Parkins, Suffolk, chairman

Dr Parkins submitted the following report:

A program subcommittee has been established to cover broadly the fields of medicine and surgery. An executive subcommittee has been established including representatives from the other New England states in order that the assembly may continue to be the New England Postgraduate Assembly rather than a local one. The committee anticipates that the assembly will be held in the fall and that choice of date and arrangements of the details of the program will soon be completed. This report is submitted for information and makes no recommendation.

Dr Parkins supplemented this report by saying that the Assembly would be held on October 30 and 31, 1946, at a place not yet determined. He added that, during the course of the assembly, there would be

a symposium on the care of the veteran throughout the English-speaking world.

Dr Parkins moved the acceptance of the report. This motion was seconded, and it was so ordered by vote of the Council.

Representative to the Hospital Council of Boston — Dr William E Browne, Suffolk

The following report was offered by Dr Browne:

Your representative has attended one meeting of the Hospital Council of Boston during the past year. At this meeting the general problem of professional charges to ward patients in hospitals was discussed. In certain hospitals no charges are made for the professional care of such patients, and in other hospitals, under certain conditions, a charge for such services is regarded as proper. The problem was presented whether any rule on this matter could be formulated. Your representative expressed the opinion that the establishment of any general rule should not be attempted, the problem varied so much in each hospital as to make it seem wise to leave the affair in the hands of the hospital and to encourage each hospital to establish such policies in the matter as best met its own needs.

Your representative believes that the Society should continue to have representation on this Council. In this way can the viewpoint of the practicing physician — the most important component part of the Society — be kept before a group of individuals especially interested in broad hospital problems.

Dr Browne moved the acceptance of the report. This motion was seconded, and it was so ordered by vote of the Council.

Representative to the Massachusetts Nursing Council for War Service — Dr David D Scannell, Norfolk

The following report was offered by Dr Scannell:

During the past two years your representative has been notified of three meetings of the Council, which he attended. The Council now plans to change its name to the Greater Boston Nursing Council and to continue under a new constitution and by-laws. Since representation to the Massachusetts Nursing Council for War Service appears no longer necessary, your representative respectfully requests his discharge from this position.

Dr Scannell moved the acceptance of the report. This motion was seconded.

The President called on the Secretary for such comment as the Executive Committee might wish to make regarding this report.

The Secretary replied that the Executive Committee recommended that this representation be abolished.

The question, as put by the President, was on the acceptance of the report and the adoption of the recommendation of the Executive Committee. It was so ordered by vote of the Council.

Committee of Seven Appointed to Nominate a Director of Medical Information and Education — Dr Elmer S Bagnall, Essex North, secretary

The report, which is as follows, was offered by Dr Bagnall:

The Council of the Society voted on October 3, 1945, that a new position be created whose incumbent shall be known as the director of medical information and educa-

The treasurer of the Society, Dr Ehot Hubbard, Jr., compared the expenditures of the Society during the last three years. He said that in 1944 they were \$38,544, in 1945, \$42,537, and that in 1946 the hudget stood at \$60,000. He expressed it as his helief that at least an increase of \$5 per year was necessary if the Society was to continue with plans already laid out. Dr Hubbard also expressed it as his belief that, should an increase in dues be ordered, an increased allocation of funds should be made to the distinct societies.

Dr Walter G. Phippen, president of the Boston Medical Library and a member of the Executive Committee from Essex South District Medical Society, expressed himself as in favor of the proposed increase, believing that of the \$20.00 so collected, \$5.00 should be allocated to the Library for the purpose of making it possible for this institution to serve the physicians of Massachusetts better. He said that, although the Library was most anxious to enlarge its scope of benefits, it found itself in such a financial position as to preclude this possibility.

The allocation of \$5.00 per member would make it possible for the Library to serve what it regards as its real purpose.

Dr Phippen, in speaking of the historical aspects of the Library, said that it was instituted in 1805. He said that it was the third largest medical library in the United States, with nearly 200,000 volumes and 135,000 pamphlets. The value of the Library contents he estimated as probably more than one million dollars.

He said it should be a modern research library, with modern conveniences for study. It should have a well-trained staff of sufficient size to give expert bibliographical aid to all members of the profession, to students and to research workers. This function it cannot perform because it has grown so fast that it has outgrown its financial means to do so.

Dr Phippen said that the present income of the Library is about \$30,000 per year and that an additional \$30,000 is needed.

He pointed out that in a survey of the Library in 1941, Thomas F. Fleming, medical librarian of Columbia University, indicated that the future of the Library hinged on its development as a reference library not only for the benefit of Boston but also for that of the rest of Massachusetts and New England.

Dr Phippen expressed the thought that if the books, which now more or less clutter up certain rooms, might be properly stacked, these rooms might become available for Society committee purposes.

The Secretary moved the adoption of the recommendation. This motion was seconded, and it was so ordered by vote of the Council.

The Secretary read the following letter addressed to the President:

AMERICAN ACADEMY OF PEDIATRICS
MASSACHUSETTS STUDY OF CHILD HEALTH SERVICES
319 Longwood Avenue Boston
Telephone BEAcon 3911

April 18 1946

Dr Reginald Fitz, President
Massachusetts Medical Society
8 The Fenway
Boston Massachusetts

Dear Dr Fitz:
Following up our conversation of last week, I should like to ask you or someone you might appoint to sit on the Advisory Committee of our study. It is planned that the committee will meet twice at the most and the first meeting will be on Wednesday, May 1, at the DuBarry Restaurant, 159 Newbury Street, at 12:30 p.m.

Sincerely yours,
(Signed) LEADON SVEDEKER
Executive Secretary

Under the rules, the President referred this communication to the Committee on Public Relations.

The Secretary read the following letter from Dr George F. Lull, secretary of the American Medical Association:

April 9, 1946

TO THE SECRETARIES OF THE CONSTITUENT STATE MEDICAL ASSOCIATIONS

The Committee on National Emergency Medical Service of the American Medical Association, which was appointed in accordance with recommendations of the Board of Trustees adopted by the House of Delegates at its meeting held in December, 1945, has requested the Board of Trustees to give them permission to suggest that each constituent state medical association appoint a similar committee. This request has been approved by the Board. The recommendation adopted by the House of Delegates is as follows:

The Board of Trustees would recommend to the House of Delegates that it authorize the Board of Trustees of the American Medical Association to appoint a committee of seven to be known as the Committee on Military Service. This committee shall include four civilian physicians who served in the war and three others. The committee will study the many communications that have been received and the suggestions made by physicians in the armed forces. The committee will also formulate policies for recommendations to be forwarded through the Surgeons General to the Secretary of War and the Secretary of the Navy expressing the views of the medical profession in planning for proper utilization of the services of physicians in any national emergency.

The Chairman of the Committee, Dr. Edward L. Bortz, of Philadelphia, desires that as much publicity as possible be given the formation of these committees.

Very truly yours
(Signed) GEORGE F. LULL

This letter was referred by the President to the Committee on Postwar Planning.

Dr Charles J. Kickham, Norfolk, was recognized. He stated that, during one of the committee meetings of the Massachusetts Medical Society, the subject of revising upward the salaries of the Society's employees had been considered. He expressed his opinion that the rising cost of living had made such revision necessary in all walks of life. He discussed the various ways in which such a revision might be brought about.

Dr Peirce H. Leavitt, Plymouth, expressed himself as believing that, if increases in salary were authorized, such increases should be made retroactive to a certain date.

The part that the Committee on Finance played in such a proposal was discussed.

Dr Kickham finally moved that the President be authorized to appoint a special committee of three to confer with the Committee on Finance and subsequently to report the matter through the usual channels, with the idea of making any change in salaries retroactive to a certain date, if it so deemed wise. The motion was seconded, and it was so ordered by vote of the Council.

Dr Bagnall was recognized. He spoke as follows:

It appears that the time may soon come when a change in income level of those eligible for the standard Blue Shield service contract may become necessary. It would seem prudent for the Society to be ready with factual data on this subject.

He moved that the President be authorized to appoint a special committee of five for this purpose. The motion was seconded, and it was so ordered by vote of the Council.

On a motion by a councilor, which was seconded by another, the Council voted to suspend the rules so as to provide Dr Norman A. Welch with the opportunity of presenting to the Council an informational report on the Blue Shield.

Dr Welch spoke as follows:

Before Dr McCann left for California, he asked me as one of the directors of the Blue Shield, if I would present to you some information about this organization and I

Dr O'Hara replied as follows

I am sure that Dr Fitz has gone as far as anyone could, farther than I would have believed anyone could have, to ease the way and smooth the path in the legislative manner with these relics which he now hands on to me. I only hope that I may be able to approach his pattern of diligence and behavior and preparation. Those of you who know how hard Dr Fitz has worked know what a tremendous job he has done for the Society through a very difficult year. My endeavor will be to follow as nearly as I can I know many reasons why I will not be able to keep up with his example, but as nearly as I can, I shall follow the pattern that he has placed before you.

The President-Elect submitted a list of nominations to committees for the year 1946-1947. It was moved and seconded that the nominations be confirmed. It was so ordered by vote of the Council. (The members of the standing and special committees for the year 1946-1947 will appear in the proceedings of the Society in the September 19 issue of the *Journal*.)

NEW BUSINESS

The following letter from the President was received by the Secretary

Dr Michael A Tighe, Secretary
Massachusetts Medical Society
8 Fenway
Boston 15, Massachusetts

April 3, 1946

Dear Mr Secretary

Since the aims of both Blue Cross and Blue Shield have the support of the Society and since our employees are in no way protected by Social Security, may I suggest through you to the Executive Committee and the Council that henceforward the Massachusetts Medical Society adopt as a policy the payment of annual subscriptions to Blue Cross and Blue Shield for each person in our employment.

Yours sincerely,

(Signed) REGINALD FITZ, M.D., President
Massachusetts Medical Society

The Secretary said that the Executive Committee had reviewed this communication and recommended that the Council authorize the enrollment mentioned. He moved the adoption of the recommendation. This motion was seconded, and it was so ordered by vote of the Council.

The Secretary read the following letter sent by the President to Dr Francis C Hall, chairman of the Committee on Finance, and the latter's answer.

Dr Francis C Hall, Chairman
Committee on Finance
372 Marlboro Street
Boston, Massachusetts

April 3 1946

Dear Francis

Because of the urgency of the situation I am writing you at this late date requesting an extraordinary appropriation. The clerical work of the Society is increasing by leaps and bounds. To meet such needs, which I believe are entirely proper, I hereby request an extraordinary appropriation of \$3500 to be used for the employment of secretarial help.

Yours sincerely,

(Signed) REGINALD FITZ, M.D., President
Massachusetts Medical Society

April 4 1946

Dr Reginald Fitz, President
Massachusetts Medical Society
8 Fenway
Boston, Massachusetts

Dear Reg

I have your letter requesting an extraordinary appropriation of \$3500 for the employment of secretarial help to be used under the direction of Dr Tighe to take care of the increased activities of the Massachusetts Medical Society.

Of course there has been no time to call a meeting of the committee and discuss this in detail, but I am not sure that the committee would feel differently if we did discuss it. I have talked with Dr William Dr O'Brien and Dr Johnson, all members of the Committee on Finance. Dr Bancroft Wheeler will be out of town until tomorrow so that I was unable to talk with him. Those of us who have discussed the matter believe that the President and Secretary know the needs of the Society and have the interests of the Society at heart.

We therefore feel that we have no choice but to express our confidence in them and endorse their request for this extraordinary appropriation. Therefore, the Committee on Finance hereby approves this appropriation, understanding that it will be submitted to the Executive Committee and Council for approval.

Cordially yours,

(Signed) FRANCIS C. HALL, M.D., Chairman
Committee on Finance

The President called on the Secretary for such comment as the Executive Committee might wish to make regarding these communications.

The Secretary stated that the Society had but one full-time clerk, that the amount of clerical work in connection with the Society's business had increased by leaps and bounds and that the present setup was no longer adequate.

He emphasized the fact that two additional permanent clerks were needed. Reference was also made to the facts that in the past certain clerks in the employ of the *Journal* had been utilized on Society's business, that this had ceased to be a satisfactory arrangement, that reports were delayed beyond the time when they were most effective, and finally that much clerical work had to go for completion to outside secretarial offices, at great expense.

The Executive Committee recommended that the Council authorize this appropriation.

The Secretary moved the adoption of the recommendation. This motion was seconded, and it was so ordered by vote of the Council.

The Secretary, acting under the direction of the Executive Committee, made the following recommendation:

That the Council authorize the President to appoint a committee of five for the purpose of studying the question of raising the annual membership dues of the Massachusetts Medical Society and, in the event that such an increase is deemed necessary, for the further purpose of studying what part, if any, of the increase should be allocated to the Boston Medical Library.

The Secretary offered the following explanatory statement in support of the recommendation:

At a regular meeting of the Executive Committee held on January 9, 1946, a motion was made and seconded that the committee recommend to the Council that, beginning in January, 1947, the membership dues in the Massachusetts Medical Society be raised to \$20.00 per year. This subject was debated at length at that time. The subject was finally laid on the table until the next regular meeting of the committee.

During the interval between the meeting of January 9 and the one held on April 24, the President addressed each member of the Executive Committee with a request that he ascertain the reaction of the members of his district toward this proposal.

Some districts conducted a postcard survey in this matter, in others the sentiment of their respective districts was checked by word of mouth in casual contact.

The members of the Executive Committee, while expressing themselves as believing that the mounting expenses of the Society made such a move necessary, did not believe that they were sufficiently informed as to the general sentiment of the Society to make a specific recommendation to the Council along these lines.

APPENDIX NO 2

TREASURER'S REPORT

The year 1945, being the last of the war years, saw a further drop in income from dues to \$40,825 from \$41,215 in 1944. And through the canceling of the annual meeting the customary income from the Committee on Arrangements was not realized. However, a very pleasant increase occurred through the operations of the *New England Journal of Medicine* in the form of a return of \$22,800, which is not to be added to General Fund principal but to be used as income for expenditures in 1946. The Society has a right to feel proud of the continued increase in circulation enjoyed by the *Journal* under Dr Nye's management, maintained this year under rather unfavorable circumstances for production.

It is also pleasant to announce the repayment of the \$25,000 loan made by the Society to the Massachusetts Medical Service in 1942. This repayment was as of December 31, 1945, and contributes toward the relatively large cash balance reported at the end of the year, as well as toward the reduced total value of securities held in the General Fund as compared with 1944. This sum will be invested early in 1946.

In 1945, \$1312 was received for subscriptions to the *Journal* from members in service and was made over to the *Journal* as in 1944.

The income from the Building Fund securities has been added to the Building Fund principal in contrast to the procedure followed in 1944 but in line with the custom adhered to for many years previous.

The General Fund securities stand at a book value of \$142,689 and market value of \$149,353 as compared to \$167,614 and \$170,885 respectively for 1944.

The Building Fund securities for 1945 amount to \$68,027 book value and \$73,270 market value as compared to \$68,170 and \$70,858 respectively for 1944.

Endowment Fund securities have a book value of \$23,166 which remains the same as in 1944.

Income from the General Fund was \$4527 with a yield of 3.17 per cent as compared with \$3969 in 1944. Income from the Building Fund was \$2156 with a yield of 3.17 per cent as compared with \$1960 in 1944.

Profit on securities sold, called or matured, in the General Fund was \$991 and in the Building Fund was \$173.

During the year there was no change in the portfolio of the Endowment Fund securities. Changes in the General and Building funds came mostly through bonds called or matured, to replace which one issue of convertible preferred stock was bought together with \$44,500 United States Treasury 2½ per cent bonds maturing in 1972-1967, which already have a market value well above their purchase price. The Society now holds a total of \$87,900 in government bonds throughout the different funds.

Total revenue for 1945 was \$71,434 and total expenses were \$42,538, leaving an excess of revenue over expenses of \$28,896.

Total Building Fund assets amount to \$70,537, an increase of \$2330 over last year. General Fund assets amount to \$211,199, an increase of \$30,122 over last year. Endowment Fund assets remain at \$23,166, causing the Society to end 1945 with a grand total of \$304,903 assets in cash and securities, an increase of \$32,452 over 1944.

The Treasurer would like to point out recent trends in the Society's activities that cause changes in the financial picture. From the point of view of revenue, the largest factor is the healthy growth of the *Journal* emerging from a stage not many years ago when the Society was called upon to advance money to help promote its efforts. From the viewpoint of expenditures certain committees are largely expanding the scope of their work in the interest of education of the profession and promotion of the health and protection of the community. Barring unforeseen and extreme fluctuations in these two factors, and in anticipation of increased income from dues as members return from the services, and from the re-establishment of the annual meeting, he believes that a balance can be maintained safely from year to year, on the present basis.

He would like again to acknowledge his great indebtedness to his secretary for her incomparable aid in the function of his office and to express gratitude for the helpful assistance rendered by the entire staff of the *New England Journal of Medicine*.

A breakdown of comparative expenses for 1944 and 1945 is appended

	1944	1945

ELIOT HUBBARD, JR., Treasurer

APPENDIX NO 3

REPORT OF THE EXECUTIVE COMMITTEE

The Executive Committee of the Council reviewed all the reports contained in the circular of advance information. It noted that they were to be a large extent informational. Beyond recommending their acceptance by the Council, the committee took no action. The committee also noted, however, that certain of these reports contained recommendations and it is with these that this report will deal specifically.

Committee on Arrangements

This committee recommends that all fellows be urged to visit the commercial exhibits during the course of the annual meeting. The Executive Committee, recognizing

promised that I would. So in spite of the fact that the time is late, I will keep my promise, but I shall be brief.

At present there are approximately 275,000 participants in the Blue Shield program, and this number is increasing at the rate of 20,000 a month. This compares with 220,000 at the beginning of the year.

The plan for the additional medical care in the hospitals has been completed and I believe has received the approval of the Insurance Commissioner, through whose office all these additions to the contract must go.

Considering the national pressure for very extensive coverage of the prepayment plans, the directors of the Blue Shield have approved the plan to increase the Blue Shield field, not only to add medical coverage in the hospitals, but also to add surgical coverage in outpatient departments, homes, and offices.

The actuary of the Blue Shield and the Blue Cross feels that there will be a slight increase in rates required to cover the surgical care in the home, office and outpatient department, and this will be accomplished by an increase in the rate from 85 cents to 95 cents for a single individual, from \$1.65 to \$1.90 for a married couple, and from \$2.00 to \$2.25 for a family.

Dr. McCann is, of course, very enthusiastic about the extension of coverage to include surgery in the home, office and outpatient department.

He also wanted me to mention to the Council, although I believe this has appeared in the Treasurer's report, that the Blue Shield has returned to the Massachusetts Medical Society the \$25,000 which was advanced by the Society when this plan was formulated.

(Dr. Welch's statement was greeted with applause.)

There being no further business before the Council, the President declared the meeting adjourned at 10:15 p.m.

MICHAEL A. TIGHE, *Secretary*

fact that in the past certain clerks in the employ of the *Journal* have been utilized on Society's business, that this has ceased to be a satisfactory arrangement, that reports are delayed beyond the time when they are most effective and finally that much clerical work has to go for completion to outside secretarial offices involving considerable expense. The Executive Committee recommends that the Council authorize this appropriation.

Dues

At a regular meeting of the Executive Committee held on January 9, 1946, a motion was made and seconded that the committee recommend to the Council that, beginning in January, 1947, the membership dues in the Massachusetts Medical Society be raised to \$20.00 per year. This subject was debated at length at that time. The subject was finally laid on the table until the next regular meeting of the committee.

During the interval between the meeting of January 9 and the one held on April 24, the President addressed each member of the Executive Committee with a request that he ascertain the reaction of the members of his district toward this proposal.

Some districts conducted a postcard survey in this matter, in others the sentiment of their respective districts was checked by word of mouth in casual contact.

The members of the Executive Committee, while expressing themselves as believing that the mounting expenses of the Society made such a move necessary, did not believe that they were sufficiently informed as to the general sentiment of the Society to make a specific recommendation to the Council along these lines.

The treasurer of the Society, Dr. Eliot Hubbard, Jr., compared the expenditures of the Society during the last three years. He said that in 1944 they were \$38,544, in 1945, \$42,537, and that in 1946 the budget stood at \$60,000.

He expressed it as his belief that at least an increase of \$5.00 per year was necessary if the Society was to continue with plans already laid out. Dr. Hubbard also expressed it as his belief that, should an increase in dues be ordered, an increased allocation of funds should be made to the district societies.

Dr. Walter G. Phippen, president of the Boston Medical Library and the member of the Executive Committee from Essex South District Medical Society, expressed himself in favor of the proposed increase, believing that of the \$20.00 so collected, \$5.00 should be allocated to the Library for the purpose of making it possible for this institution to serve the physicians of Massachusetts better. He said that, while the Library was most anxious to enlarge its scope of benefits, it found itself in such a financial position as to preclude this as a possibility.

The allocation of \$5.00 per member would make it possible for the Library to serve what it regards as its real purpose.

Dr. Phippen, in speaking of the historical aspects of the Library, said that it was instituted in 1805. He said that it was the third largest medical library in the United States with nearly 200,000 volumes and 135,000 pamphlets. The value of the Library contents he estimated as probably more than one million dollars.

He said it should be a modern research library with the modern conveniences for study. It should have a well-trained staff of sufficient size to give expert bibliographic aid to all members of the profession, students and research workers. This function it cannot perform because it has grown so fast that it has outgrown its financial means to do so.

Dr. Phippen said that the present income of the Library is about \$30,000 per year and that an additional \$30,000 is needed.

He pointed out that in a survey of the Library in 1941, Thomas F. Fleming, medical librarian of Columbia University, indicated that the future of the Library hinged on its development as a reference library not only for the benefit of Boston but also for that of the rest of Massachusetts and New England.

Dr. Phippen expressed the thought that if the books, which now more or less clutter up certain rooms, might be properly stacked, these rooms might become available for Society committee purposes.

The Executive Committee, under the head of new business, will recommend that the Council authorize the Presi-

dent to appoint a committee of five for the purpose of studying the question of raising the annual membership dues of the Massachusetts Medical Society and, in the event that such an increase is deemed necessary, for the further purpose of studying what part, if any, of the increase should be allocated to the Boston Medical Library.

MICHAEL A. TIGHE, *Secretary*

APPENDIX NO 4

REPORT OF THE COMMITTEE ON MEDICAL EDUCATION

On October 17, 1945, the Council referred to this committee the following resolution, offered by Dr. Charles E. Morgan:

WHEREAS, The question has been repeatedly asked in public and private concerning the facilities for medical education in Massachusetts, and

WHEREAS, No satisfactory scientific answer has been forthcoming, therefore, be it

RESOLVED, That the Massachusetts Medical Society undertake a survey of medical educational facilities at present available in New England.

The committee has held several meetings, has consulted with the deans of several medical schools, the head of the state departments of health, other educational officials here and in the American Medical Association, and now begs to submit the following informational report.

There are five medical schools in the six New England states approved by the Approving Authority of the Commonwealth of Massachusetts. They are as follows:

	REGISTRATION OVER
Yale University School of Medicine New Haven Conn.	200
Boston University School of Medicine Boston Mass.	210
Harvard Medical School Boston Mass.	530
Tufts College Medical School Boston Mass.	410
University of Vermont College of Medicine Burlington Vt.	125
Total Registration	1475

It seems unnecessary to describe the educational facilities of these schools as to buildings, hospital affiliations, endowment, annual budgets, faculties and so forth. This information for the most part is available in the printed catalogues of the schools, which can be had on request to their deans. Their facilities are sufficient to warrant the continued approval and support of their parent university.

Medical education is expensive. The tuition fees, usually ranging from \$400 to \$600 per student per academic year, cover only a fraction of the actual cost, the rest is borne by endowments, grants from the parent organization, philanthropic and charitable foundations, or by federal, state and community funds. For comparison with the cost of other educational processes, note the following table taken from the "Educational Number" of the *Journal of the American Medical Association* for January 13, 1940.

SCHOOL	COST PER STUDENT CREDIT HOUR
Education	\$4.06
Commerce	5.92
Engineering	10.52
Law	11.05
Agriculture	14.51
Dentistry	15.87
Medicine	26.96

It is reasonable to assume that these figures would be greater today.

The high cost to the student can be offset to some degree by scholarships and grants and by part-time extracurricular employment, an expedient which is undesirable in that it takes energy from the main task of studying medicine.

Are these five schools able to create enough doctors to meet the medical needs of New England adequately? This is hard to answer, for what is adequate? Of course, New England should not be considered as a unit independent of the rest of the country, for there is a free inter-

the growing importance of these exhibits in the success of the annual meeting, approves of this recommendation and, in the furtherance of its objective, recommends additionally that the *New England Journal of Medicine* carry suitable reference to these exhibits and that the several chairmen who preside over the exercises of the annual meeting be instructed to call, at least twice daily, the attention of the gathering to them and to the importance of paying them a visit

Committee on Medical Education

This report, in a special manner, elicited the commendation of the Executive Committee. It is an excellent factual study of correlated material brought together from many sources. Its conclusions are soundly drawn. The Executive Committee was aware that the stimulus to the resolution offered by Dr Mongan, by which the Council authorized this study, largely came about as the result of inquiry by members of the Massachusetts Legislature regarding the need of additional medical schools in Massachusetts.

Because this report now makes such information readily available, the Executive Committee, in addition to recommending that this report be accepted by the Council, further recommends that the Council specifically direct the attention of the Committee on Legislation to it for such use as this latter committee may deem wise.

In so directing the attention of the Committee on Legislation to this report, the Executive Committee points out that Table 4 as it relates to the rejections, without explanation, might be subject to serious misunderstanding.

The Executive Committee would have the Council and the Committee on Legislation know that most candidates apply simultaneously to many medical schools and that those rejected by one school frequently find places in others. The Executive Committee has it on authority that a little over 50 per cent of all applicants find places in some medical school.

Committee on Public Health

The Executive Committee notes that this report contains the following recommendation: "That the president of the Society be authorized to take the initiative in aiding the four district societies concerned in selecting suitable representation on the Greater Boston Nursing Council."

The Executive Committee disapproves of this recommendation. It believes that, because of the Society's statewide character, it should not associate itself with an organization that is purely sectional in its scope and purpose.

The Executive Committee recommends that the Council reaffirm its stand in this matter as taken on October 6, 1937.

The Executive Committee further recommends that the Council instruct the Secretary to write to Miss Tracy, of the Greater Boston Nursing Council, advising her of the Society's sympathetic interest in this matter and recommending that she make contact with the district societies concerned.

Committee on Public Relations

The Executive Committee noted that this report contained one recommendation and a reference, without recommendation, to a correlated matter.

The recommendation would have the Council approve of the enrollment of the members of the Society in the Blue Cross in such a manner as is considered most efficient by the Secretary and the officials of the Blue Cross. The Executive Committee approves of this recommendation and recommends its adoption.

The Executive Committee noted that this report contained a reference to a similar enrollment of the members of the Massachusetts Medical Society in the Blue Shield. It also noted that the Committee on Public Relations was unwilling to take a stand on this matter because of the possible involvement of one of the Society's traditions whereby one physician cared for another or another's dependents without charge.

In the discussion attending this subject before the Executive Committee, Dr Milton Quinn was heard. He believed that many members of the Society were overburdened by the care of other physicians and their families. He saw

no reason why individual members of the Society might not join the Blue Shield if they so desired. The question at issue, as he defined it, was whether or not the Massachusetts Medical Society should endorse their joining.

In connection with the subject, Section 2, Article II, of the "Principles of Medical Ethics" of the American Medical Association was read into the record. This section reads as follows:

When a physician from a distance is called on to advise another physician or one of his family dependents, and the physician to whom the service is rendered is in easy financial circumstances, a compensation that will at least meet the traveling expenses of the visiting physician should be proffered. When such a service requires an absence from the accustomed field of professional work of the visitor that might reasonably be expected to entail a pecuniary loss, such loss should, in part at least, be provided for in the compensation offered.

It was pointed out that at least inferentially, except under the circumstances outlined, this section indicates that it is not considered good medical ethics for one physician to charge another for services rendered.

The Executive Committee offers no recommendation regarding this matter.

Committee on Legislation

The Executive Committee believes that the Committee on Legislation acted with wisdom regarding the matters outlined in its report.

Massachusetts Delegates to the Council of the New England State Medical Societies

The Executive Committee directs the attention of the Council to a typographical error occurring in this report, "1946" should read "1945."

The Executive Committee recommends, subject to the approval of the Committee on Finance, that the sum of \$100 be set aside to cover the expenses of the Council, a like amount being contributed by each of the state medical societies concerned.

Representative of the Massachusetts Medical Society on the Massachusetts Committee for Nurses Procurement and Assignment Service

The Executive Committee recommends that this representation be abolished.

Representative of the Massachusetts Medical Society to the Mental Health for Victory Organization

The Executive Committee recommends that this representation be abolished.

Representative to the Massachusetts Nursing Council for War Service

The Executive Committee recommends that this representation be abolished.

Nominations

The Executive Committee reviewed certain committee nominations made by the President-Elect for the year 1946-1947 and recommends their approval by the Council Communications.

The Executive Committee reviewed a communication concerning an enrollment of the employees of the Society in the Blue Cross and Blue Shield. The communication was received by the Secretary and signed by the President. The Executive Committee recommends that the Council authorize this enrollment.

The Executive Committee reviewed a communication addressed to Dr Francis C Hall, chairman of the Committee on Finance and signed by the President, and Dr Hall's answer. In this communication, the President requests an extraordinary appropriation of \$3500 to be used for additional secretarial help in the Society's offices. In supporting this appropriation, the President pointed out that the Society has but one full-time clerk, that the amount of clerical work in connection with the Society's business has increased by leaps and bounds and that the present setup is no longer adequate to meet our needs. It was emphasized that two additional permanent clerks are needed at the present time. Reference was made to the

Table 4 shows the rejection rates for applicants to the medical schools in this area in a recent six-year period. The total number of candidates varies greatly, the number accepted (one fifth to one half) remains constant for a

ratio of physicians to population in this country, as shown in Table 1. To increase this to any large extent would be costly and not in the interests of the public welfare. We do not need more doctors, we need better doctors, rather

than a flood of mass-produced and hence inferior doctors. We must conclude on such evidence that New England does not now need a new medical school, and that its present schools can meet the medical needs of the anticipated growth in population in this area for the next several years. Were any new school to be developed, we believe that it could be placed more advantageously and usefully

ROBERT T. MONROE, Chairman

APPENDIX NO 5

REPORT OF THE COMMITTEE ON PUBLICATIONS

The Committee on Publications has secured Dr. John B. Youmans, associate professor of medicine at Nashville, Tennessee, and recently serving as a colonel in the Medical Corps of the United States Army and chief of the Nutrition Branch of the Office of the Surgeon General in Washington, to deliver the Shattuck Lecture at the annual meeting of the Society in 1946.

The Directory of Fellows has been printed and distributed in accordance with the vote of the Council.

The accounts of the Journal have been audited by Hartsorn and Walter and found to be in order. An abstract of this report is appended and copies of the full audit have been filed with the Treasurer and the Committee on Finance.

The committee has continued to supervise the publication of the New England Journal of Medicine. The Journal has prospered under the able direction of the managing editor, Dr. Robert N. Nye, with the assistance of Miss Davies, the associate editors and the members of the Editorial Board. The Society has reason to be proud of what has been accomplished. In reporting to the Council this phase of the committee's duties we quote from the report made by Dr. Nye to the committee:

During 1945, the New England Journal of Medicine experienced its best year under ownership by the Massachusetts Medical Society. The circulation continued to increase and, because of this, operations were profitable. New subscriptions for the year totaled slightly less than those for 1944, the respective figures being 5913 and 6109. On the other hand, cancellations were fewer in 1945 than in 1944, so that the net increase in circulation was the largest in the history of the Journal. As of December 31, Journals were being sent to 4398

change of students. And the question should be separated as much as possible from issues such as distribution of physicians and volume of student applications.

It would seem reasonable to assume that if the proportion of physicians in the population over a fair number of years remains stable, that proportion is probably acceptable ("adequate") in terms of public need. If it rises, increased need would appear to have been felt and met, if it falls, the saturation point must have been reached.

On this assumption, the sample figures in Table 1 were assembled from the *American Medical Directory*, the *Year Book of Facts* and the reports of the United States Census. It is seen that, over a period of twenty-four years, the population of the United States increased over 26,000,000; the number of physicians increased over 41,500, but that

TABLE 1 Proportion of Physicians in the Population of the United States and New England

	POPULATION (APPROX.)	NO. OF PHYSICIANS	PHYSICIANS PER 1000 POPULATION

(Portland)	73,600	166	2.252
Rhode Island	713,300	958	1.344
Vermont	359,200	551	1.536
New England	8,436,200	13,012	1.543

the number of physicians for each thousand persons changed very little, — from 1.408 in 1918 to 1.443 in 1942. Expansion of medical educational facilities has kept even pace with increase in population. Therefore, it would appear that this proportion of physicians is about what the public asks for, at least at its present level of appreciation of need.

New England has a higher ratio of physicians to population than the rest of the country in every sampled year.

In 1918, it had 1.541 physicians per thousand population; in 1921, it had 1.462, in 1931, it had 1.426, in 1936, it had 1.519, and in 1942, it had 1.543. Massachusetts persistently has had a higher ratio of physicians to population than any other New England state except for Vermont in 1918. Their uneven distribution between towns and cities, however, is plain — in Boston greatest of all, perhaps because it is the chief center of medical education for the area.

Another fact that emerges from Table 1 is that the states which have medical schools maintain a higher proportion of physicians than those which do not. This has been true of Massachusetts and Vermont for many years. Connecticut had a low physician ratio in 1918 and 1921 but attracted more doctors than population thereafter. On the other hand, Rhode Island has been low in physicians in ratio to population in four of the five sampled years and equaled the national average only once, and Maine has been low every year.

Finally, Table 1 suggests that there is no present need for the establishment of a new medical school in Massachusetts, or even in New England. Harvard and Yale being national schools, take large numbers of students from beyond New England, but Tufts, Boston University and Vermont give distinct preference to in-state and New England residents.

As the population of New England increases, more physicians must be trained. At some time in the future, therefore, the question must be faced whether it will be better to expand the existing educational plants or to arrange for the development of one or more new schools. Various considerations will have to be weighed carefully, such as the financial expense, the ideal size of a medical school, the existent clinical facilities, and the needs of the community. The conclusions of the Council on Medical Education and Hospitals as published in the *Journal of the American Medical Association* for September 1, 1945, show much common sense. A few are quoted.

Any overall increased present or postwar need for additional physicians occasioned by the war can be provided by existing approved schools. There is no justification for establishing new medical schools for this purpose. Furthermore, the normal annual number of graduates from existing schools is adequate for the peacetime needs of the country, granted distribution is equal.

The maldistribution of physicians as between the states or between urban centers and rural areas is a problem to be attacked primarily by other means than the production of more doctors in a given state, the rate of production and the distribution of doctors in this country are independent.

Medical education is by far the most expensive form of professional training, requiring an initial outlay and subsequent annual budgets in the early years totaling millions of dollars and not tens or hundreds of thousands. A school whose resources include annual budgets of less than \$350,000, independent of the cost of maintenance of the hospital and out-patient departments, is unlikely to conduct a satisfactory program.

The medical educational facilities in New England and all over the country are inadequate in the opinion of the college student, for there are only about half as many places in schools as there are applicants for them. Dr. Fred C. Zappfe's annual reports in the *Bulletin of the Association of American Medical Colleges* show, for the years 1933-1942, applicants varying from 11,800 to 14,043, with 50 per cent acceptances. Many candidates seek to assure themselves of a place by applying to several schools at once. The figures of recent years for our territory are shown in Table 2. The volume of applications does not show a significant upward trend, though there is a suggestion that it decreases in good business years and increases in bad years.

Table 3 shows that New England takes care of the same proportion of its students wishing to enter medicine as does the rest of the country. Massachusetts and Vermont do distinctly better than that. Connecticut students go in greatest number to nearby New York. Students from our two states without medical schools show a slight preference for schools outside of New England.

Pharmaceutical Association and the New York State Medical Society and State Board of Pharmacy, regarding existing laws and regulations bearing on harbiturates, sulfonamides, penicillin and so forth

We find that under federal law, harbiturates cannot be sold without a doctor's prescription. Refills may be dispensed by the druggist unless the doctor has otherwise directed. The active director informs us that with only about two hundred inspectors to cover the whole field of food, drugs and cosmetics, there can be no adequate coverage of the practices of fifty thousand retail drug-stores. He expresses the hope that because this is primarily a local problem, the drug industry will concern itself with corrective measures. The druggist would like the co-operation of the medical profession particularly by stating on the prescription whether or not and how many times refills are authorized in each instance. "N R" would mean no refills.

In New York City and New York State, there are regulations under the law which are aimed at controlling abuses. In Massachusetts there appears to be opinion that legislation is needed, but there is not yet agreement that the public interest would be best served by seeking legislation now.

The new labeling regulations under the federal law have just become effective and it was agreed at a conference on December 17, 1945, that we should await the experience under that regulation before taking action in this state. This conference included the Commissioner of Health, the secretary of the Board of Registration in Pharmacy, the president and legal counsel of the Massachusetts Pharmaceutical Association and our committee. The pharmacists expressed their gratification for this co-operation in approaching solution of mutual problems.

ELMER S BAGNALL, *Chairman*

APPENDIX NO 7

REPORT OF THE COMMITTEE ON POSTWAR PLANNING

Postgraduate courses planned by the Subcommittee on Postgraduate Medical Education have been conducted throughout the State as follows:

District No 2 — Springfield, Holyoke, Northampton and Greenfield — two courses

District No 3 — Worcester, Gardner, Fitchburg and Leominster — two courses

District No 4 — Lowell, Haverhill, Lawrence and Newburyport — two courses

District No 5 — New Bedford, Fall River and Hyannis — one course

District No 6 — Beverly, Salem, Lynn, Danvers and Gloucester — five courses

District No 7 — The Greater Boston Area. In this area a comprehensive postgraduate lecture course, open to every licensed physician in the Commonwealth, meeting each Monday and Wednesday, has been in progress since February 18 and will continue to May 15, 1946. Over a thousand doctors have registered for this course and to date the average attendance at each meeting has exceeded five hundred.

In District No 1 — Pittsfield, North Adams and Wilmamstown — courses are in preparation.

Through the efforts of the subcommittee on Veterans' Affairs information has been obtained in regard to the need of returning medical veterans for office space, industrial opportunities, assistantships, hospital facilities for the care of their patients and opportunities for a return to practice. Replies to a questionnaire submitted at the postgraduate course in Cambridge indicated that there is no urgent need at present for taking any active steps to secure office space for doctors. Physicians willing to share their offices temporarily might be listed at the headquarters of the Society. Any older physicians wishing a young doctor as an assistant may also find help at 8 Fenway through the Bureau of Clinical Information. All returning physicians are concerned about the impossibility of getting telephone listings before December when the new directory is issued. Information regarding the efforts which the New England Telephone Company is making to aid

this problem will be published in the *New England Journal of Medicine*. It is apparent that there will be a need for the continued and enlarged activities of the Bureau of Clinical Information at 8 Fenway to give aid to returning veterans for a period of several years. The questionnaire sent out by the American Medical Association in relation to opportunities for physicians has not been properly filled out by all the eighteen district societies with the result that at 8 Fenway inadequate information is available for those doctors seeking information about opportunities for practice in various parts of the State.

Conference with officers of the Massachusetts Hospital Association was held with regard to providing hospital appointments for veterans.

HOWARD F ROOT, *Chairman*
LEROY E PARKINS, *Secretary*

APPENDIX NO 8

REPORT OF THE COMMITTEE ON LEGISLATION

The committee, representing the eighteen district societies, has had two meetings. In order to facilitate action it has delegated powers to a small executive subcommittee, which has held four additional meetings. Mr Charles J Dunn has been appointed legislative counsel.

Federal activities have been chiefly confined to Senate 1606 and its satellite bills. Dr Reginald Fitz was appointed to represent the Committee on Legislation at the legislative hearings at Washington in co-operation with Dr Elmer S Bagnall, the representative of the Council of the Massachusetts Medical Society. Later, at the request of Dr Joseph S Lawrence, of the American Medical Association, a special committee of five — Drs Reginald Fitz, Elmer S Bagnall, Michael A Tighe, Dwight O'Hara and James C McCann — was appointed to handle all federal legislation. Senator Murray stated recently that it would not be possible for state medical societies to be heard at these hearings, but that they were invited to submit statements in writing. Such a statement, embodying the views of the Massachusetts Medical Society, has been sent to Senator Murray.

The usual perennial bills with a sprinkling of new ones have been presented to the Massachusetts Legislature. Your committee has reviewed some sixty-nine bills relative to medicine and public health, and has voted to approve thirteen, to oppose fifteen, and to take no action on forty-one. Most of these bills have now been heard before their respective legislative committees. At the hearings on important bills the Massachusetts Medical Society has been represented by its legislative counsel, by the chairman of the Committee on Legislation or by selected speakers.

The present status of some of the more important bills is as follows. The adverse reports of the legislative committees on the bills on antivaccination and the special board of osteopathy have been accepted by the Legislature. A special committee, with members from the three medical schools and hospitals, ably handled the anti-vivisection bills. A resolve to set up a recess committee to investigate animal experimentation, which was substituted for the adverse report of the Committee on Legal Affairs on H R 117, was defeated by a narrow margin in the Senate. The two other antivivisection bills have not as yet come up for final disposal by the Legislature. The bill for reciprocity with other states in licensing physicians has been favorably reported and is now before the Ways and Means Committee.

At the present time bills relative to the following subjects are still in the legislative committees: (1) changes in the requirements for admission to examinations for license to practice medicine, (2) revocation of charters for nonfunctioning and poorly functioning medical and osteopathic schools, (3) the opening of hospitals to any licensed physician, and (4) the establishment of a special chiropractic board.

The Committee on Legislation has considered two matters referred to it by the Council at its meeting on February 6, 1946.

members of the Massachusetts Medical Society, 362 members of the New Hampshire Medical Society, 9766 regular subscribers, 3263 medical students and 299 miscellaneous readers, — a grand total of 18,088 copies, which represents an increase of 3203 for the year.

During 1945 the *Journal* received no money from the Society except those sums paid to the treasurer for subscriptions to the *Journal* by members in the armed forces. In spite of this, cash on hand as of December 31, 1945, amounted to \$28,977. A check for \$22,800 was turned over to the treasurer of the Society.

During 1945, the editorial board considered 203 manuscripts, of which 129 were accepted for publication. The corresponding figures in 1944 were 194 and 151.

Last fall all limitations on paper were removed. This was fortunate, since the allotted tonnage for the fourth quarter would not have sufficed and an ex-quota allowance over and above that already granted would have been necessary. Since then, the weight of the paper has been increased from forty to fifty pounds, more coated stock has been used, and the pagination has been increased. By the end of 1946, it is hoped that the grade of paper will improve and that the pagination can be increased to the prewar level.

Difficulties regarding printing of the *Journal* still exist. Although at one time last summer copies of certain issues were placed in the mail within a day or so of the date of publication, the spread gradually increased, and at the end of the year copies were being received about two weeks after the date of publication. Furthermore, the delivery of reprints has been held up to such an extent that it is difficult to appease the authors. The delay in printing the *Journal* is due partly to failure to deliver copy according to schedule and to last-minute changes, and partly to difficulties in the printing plant — one of the latter being the time required to run through issues that contain three or four different colors in the advertising pages. It is hoped that these matters can be adjusted during the current year. The press-work continues to be excellent.

With the increase in circulation, particularly at a time when the addresses of those in the armed forces are continually changing, the time required to handle the mailing list is the major item of the office staff. Undoubtedly this will taper off as physicians adopt permanent residences, but at the moment it necessitates almost superhuman effort. To this has been added an increasing amount of work for officers and committees of the Society, and, in spite of adding one girl to the office staff, Miss Davies and her assistants are still overwhelmed. That they are able to complete what they are asked to do is a miracle, and for this they again deserve the highest commendation.

Although the *Journal* can function during 1946 with the space now available, additional room *must* be provided by 1947. If the rooms now occupied by the Society were obtainable, space would be ample.

The outlook for 1946 appears excellent, so far as the editorial department of the *Journal* is concerned. More papers are being submitted for publication, which will permit the editorial board to be somewhat more critical in their acceptance than it has in the past two or three years. On the other hand, the cost of publishing the *Journal* will markedly increase, largely owing to an increase in the per-pound cost of paper and an approximate 50 per cent increase in tonnage, due to heavier stock and increased pagination. This increase will be somewhat offset by higher advertising rates, but it seems likely that, with the cancellation of the 90 per cent excess profits tax, many of the pharmaceutical houses will curtail their advertising programs. Although the circulation will undoubtedly increase, the increases of the past two years cannot be expected. Consequently, although the *Journal* will probably continue to be profitable, a sum of \$5000 has been requested in the current budget.

APPENDIX NO. 6

REPORT OF THE COMMITTEE ON PUBLIC HEALTH

This committee presents herewith the report of Dr. Elmer S. Bagnall's subcommittee which has considered state legislation to control the dispensing of certain drugs.

This report is informational only but well worth the careful reading by every member of the Society.

The President referred to this committee a request from Miss Margaret H. Tracy of the Greater Boston Nursing Council that the Society appoint a representative to sit on their council. The Council of the Massachusetts Medical Society on October 6, 1937, rejected a similar request because it felt that the Massachusetts Medical Society should not, as a state organization, enter into a purely local problem. The Committee on Public Health recognizes the value of public relations and the necessity of approving such projects as may be sponsored by the Greater Boston Nursing Council, inasmuch as they relate largely to problems of medical interest. Your committee feels that it will be much more logical to approve their programs before they are inaugurated and co-operate with the Greater Boston Nursing Council, rather than have no voice in the formation of its policies. Your committee is of the opinion that such procedure will result in better public relations, better understanding and better co-operation with a closely allied profession. The committee therefore recommends that the president of the Society be authorized to take the initiative in aiding the four district societies concerned in selecting suitable representation on the Greater Boston Nursing Council.

There has been some delay in the appointment of the subcommittee to study ways and means to improve the medical health services to the schools.

We hope that before the annual meeting this committee will be in action and ready to report in the fall.

ROY J. WARD, *Chairman*

REPORT OF THE SUBCOMMITTEE TO CONSIDER STATE LEGISLATION TO CONTROL DISPENSING OF CERTAIN DRUGS

Your committee has inquired from the Federal Food and Drug Administration in Washington, the Massachusetts Board of Registration in Pharmacy and the Massachusetts Department of Public Health, as well as the Massachusetts

This was the first meeting in one and a half years — much too long an interval — since so many things of very great importance were required to be discussed and acted on, and it must be remembered that the House of Delegates determines the policy of the American Medical Association and the trustees merely carry these policies out. Incidentally, it was proposed and will be voted in July next to have two meetings of the House of Delegates a year, one at the regular convention time and the other in mid-winter, presumably in Chicago.

There was an unusually good attendance (171 out of 176), really remarkable when one considers the difficulties of traveling and securing hotel accommodations. One comes back always from these meetings with renewed convictions that this is a real medical democracy, without pressure groups or blocs, composed of the very best men from all over the country who have only one thing in mind, the furtherance of medicine.

We went through three really very intense days without any breaks, one got the impression that we were attempting to do rather too much in too short a time. As an explanation of that, however, was the feeling that we were uncertain as to what was the opinion in Washington, when the hearings on the various compulsory sickness insurance bills were coming up, and the collateral lay pressure as shown, for example, in the rather large advertisement in the *New York Times* and other big metropolitan dailies appearing almost simultaneously with our meeting. These advertisements contained the names of three or four hundred prominent people in national life and various large business concerns, all endorsing President Truman's health message. These influences unquestionably had some effect in making the House of Delegates work under pressure.

The usual addresses of the President and the Speaker were read but easily the best address was one given by President-Elect Roger Lee on the second evening of the meeting, the subject being, "What Is Medical Care?" His address deserved a much larger visual audience. I say this without prejudice and uninfluenced by any affection or local pride. In the absence of a large American Medical Association meeting, the audience on the evening of the second day was rather small and the address was not broadcast but it was printed in the December 15 issue of the *Journal of the American Medical Association* and should be read by everyone. As a matter of fact these addresses, those of the President, the President-Elect and the Speaker, should be read by all members. These appear under the minutes of the meeting in the December 15 and 22 issues. Obviously these addresses are much too long to review in even summary.

The organization of the American Medical Association House of Delegates calls for many reference committees, this year fourteen of them. To the reference committees are referred by the Speaker the business matters as they turn up. The members of these committees work long and late, particularly this year. Of our delegates, Walter Phippen was chairman of the important Reference Committee on Medical Care of Veterans, with Leland McKittrick as associate. Also co-operating on that committee was Henry Viets, section on nervous and mental diseases. The report of Dr. Phippen's committee was splendidly done and well received. (At this point I should say that in our opinion there would have been no difficulty whatever in Dr. Phippen's being elected a trustee had he cared to serve, he is well known and highly thought of, and we were prepared to nominate him up to the very last moment had he chosen to stand for election, but he felt that he could not afford the time. In his place Dr. James R. Miller of Hartford, Connecticut, a most able man, was elected without any difficulty.) Dr. Dwight O'Hara served well and conscientiously, as always, on the Committee on Reports of the Board of Trustees and Secretary.

I need not discuss how these reference committees sit in various outside rooms and listen to the pros and cons in any measure that comes up. Suffice to say that the members work conscientiously and well, and it devolves on the chairman of each committee to write up the report of his committee and present it to the secretary after being read in the House of Delegates as a whole. I do not remember, in my experience, that I have ever known reference committees to work as they did on the occasion of this meeting.

Now as to the highlights of our first day the December 1 issue of the *Journal of the American Medical Association* was distributed to the members the day before you received your copies here, with the splendid and logical editorial "The Present National Health Problem and the New Wagner Bill." As said above, almost coincidentally with this meeting a large paid advertisement appeared in the *New York Times* and other metropolitan dailies, obviously having in mind an offset to the meeting of the House of Delegates. There can be no question that these things hung like a shadow over the meeting and made for increased pressure. Unquestionably these various activities accelerated moves to put out voluntary prepaid medical care measures and the correlation and co-ordination of them countrywide to demonstrate what could be done in that way. As we know, there are about fifty-nine different plans for medical service, in twenty-five different states at the present time, and an attempt must be made to get these into some more or less general scheme of efficiency.

Without question the appearance of General Hawley of the Veterans' Administration was most happy and stimulating. He is a wholesome, forthright, understanding and sympathetic man, and his address before the House of Delegates, published in the December 22 issue of the *Journal of the American Medical Association*, deserves most careful reading.

Other things of interest were the following recommendation of the transfer of the Children's Bureau from the Department of Labor to the Public Health Service, organization of a new section on general practice, approval of a national research foundation under the control of a board of directors composed of scientists, recommendation of the appointment of a Medical Cabinet officer, unanimous adoption of a proposal to create a national medical plan to provide voluntary sickness insurance for all Americans at cost, within their means, fostering the development of this insurance in areas where there are none such, the Council on Medical Education and Hospitals of the American Medical Association does not intend to remove any hospital from its list of hospitals approved for internships or residencies which furnishes teaching facilities to any veteran medical officer who is eligible for educational benefits under the Servicemen's Readjustment Act, — provided the veteran is legally eligible for medical licensure in the state in which the hospital is located, and disapproval of Senator Pepper's super-EMIC program, which would have allowed the Children's Bureau to provide free medical care for every United States child under twenty-one and for every United States woman during pregnancy. Also disapproved were those portions of the Wagner-Murray-Dingell bill which would have had the effect of socializing medicine.

The members should read the excellent article "Medical Care for the American" by Dr. Louis Bauer in the December 1 issue of the *Journal of the American Medical Association*. This is a most helpful article and represents a lot of thought on the part of the committee of which he was chairman.

Great pride was felt by all of us in the selection of Dr. George R. Minnt for the Distinguished Service Medal, particularly when only a few years ago Dr. Elliott P. Joslin was the recipient.

George Lull was appointed as assistant to Olin West and probably his successor. Dr. Lull impressed everybody at the meeting with his extremely great capabilities. He is a straightforward, entirely capable man, succeeding, however, a man whom the American Medical Association can badly do without — Olin West. Olin West is a name to most doctors but personally he is a tower of strength to the organization and it will be a sad day when he gets out. His health is not too good and has not been for the last couple of years.

The resignation of Speaker Shoulders was rather dramatic and unexpected. He was promptly nominated, however, for the position of president-elect and in a rather close election beat out E. J. McCormack, of Toledo, Ohio, another extremely able man and a most active member of the House of Delegates, the vote was 77 to 51. Dr. Shoulders has been speaker for many years and is a hard worker and a capable man. Last year you will remember, in order to have Dr. Lee become president-elect, his resignation as a trustee was asked for (by agreement) so that he might

The first was "that the Massachusetts Medical Society send a return postal card to all members of the Society on the Wagner-Murray-Dingell Bill (Senate 1606) requiring a 'yes' or 'no' answer as to whether or not they favored this legislation."

After due discussion, the committee voted not to make a poll of the Massachusetts Medical Society in respect to Senate 1606. The committee believed that such a poll would be ineffective since a previous poll on HR 1328 resulted in only about one fifth of the members voting. Also the results would be misleading because those who favor such legislation would vote, and those who were opposed would be less likely to reply. Furthermore, a divided vote would not strengthen the position in Washington of the representative of the Society, who now has definite instructions from the Council to oppose S 1606.

The second matter referred to the committee by the Council is as follows:

That it is the sense of the councilors of the Norfolk District that a list of the final vote of the Massachusetts Legislature on the Chiropractor Bill of 1945, be published in the *New England Journal of Medicine*, this list to be published by districts rather than alphabetically, and if space is difficult to obtain, that it be published in several successive issues a few districts at a time.

After careful deliberation the committee voted unanimously to disapprove of publishing such a list. It was felt that its publication would seriously interfere with the efforts of the committee in changing the votes of members of the Legislature in respect to this bill, and Mr Charles J Dunn, the legislative counsel for the committee, advised against such publicity as seriously hampering his work.

DAVID L. BELRING, *Chairman*

APPENDIX NO 9

REPORT OF THE MASSACHUSETTS DELEGATES TO THE COUNCIL OF THE NEW ENGLAND STATE MEDICAL SOCIETIES

The Council of the New England State Medical Societies was formed in the summer of 1945. Its organizational meeting was held in Providence, Rhode Island, on July 18, 1945. The Massachusetts Medical Society was represented at this meeting by Dr Dwight O'Hara, president-elect, Dr Allen G Rice and Dr Michael A Tighe, secretary of the Society.

All the state medical societies of New England were represented.

The purpose of the Council, as outlined by the temporary chairman, Dr John F Kenney, of Pawtucket, was to bring about a closer co-operation between the state medical societies of New England in the development and maintenance of the highest standards in the conduct and administration of medical care, in the development of plans relative to the better organization of medicine and in the furtherance of plans to improve the health of all the people in the New England states.

He added that the Council shall not be concerned with the problems that are peculiar to the individual state but shall deal with the larger matters in which all the state medical societies of New England are concerned.

He emphasized the fact that the Council shall not seek to supersede the control now exercised by the governing bodies of each respective state medical society, or that of the House of Delegates of the American Medical Association.

The annual meeting of the Council was set for the third Wednesday in April of each year. Other meetings were provided for at the call of the president of the Council.

It was decided at this meeting that the Council would take no stand on any matter before it unless the will to do so was unanimous.

It was voted that each of the New England state medical societies be asked to support this Council as an experiment for one year by the contribution of one hundred dollars. The method by which the Council would be financed beyond this time was left for a future time.

The following officers were elected to serve until the third Wednesday in April, 1946:

Dr James R Miller, *President*
Dr John F Kenney, *Vice-President*
Mr John E Farrell, *Executive Secretary-Treasurer*

The Council held its second meeting in Providence, Rhode Island, on October 14, 1945.

At this meeting the Council voted to join the New England Council — an organization for the most part concerned with the business interests of New England.

The need for a program by the civilian doctor, whereby the veteran could obtain the medical care to which he was entitled under the law, was discussed.

The importance of informing the public with regard to pending legislation was stressed.

Medical-care plans came under discussion.

The Council met again on February 3, 1946. This meeting was held at 8 Fenway, Boston. The special guests of the Council on this occasion were the president of the American Medical Association and certain members and associates of the Council on Medical Service and Public Relations of the American Medical Association.

The program of this meeting was as follows:

PROGRAM

- 1 15 p m Registration
- 1 30 p m Call to order
Presiding James R. Miller, M D, president, Council of the State Medical Societies of New England trustee, American Medical Association
- 1 40 p m Greetings to Conference
Roger I Lee, M D, president, American Medical Association
- 1 50 p m "The Work of the Council on Medical Service and Public Relations of the American Medical Association"
"Prepayment Medical Care Plans" Mr Jay Keisner, executive vice-president, Michigan Medical Service, chairman, Advisory Committee on Prepayment Medical Care Council on Medical Service and Public Relations.
"Fourteen Point Constructive Program for Medical Care." Louis H Bauer M D member of Council on Medical Service and Public Relations trustee, American Medical Association
- 2 20 p m Discussion
- 2 40 p m "The Returning Veteran and the American Medical Association" Major General George F Lull, M C.
- 3 00 p m Discussion
- 3 10 p m "The Washington Front." Joseph S Lawrence M.D., director of the Washington Office of the Council on Medical Service and Public Relations of the American Medical Association
- 3 30 p m Discussion
- 3 45 p m "The Hill-Burton Bill and the Hospital System" Fitz Arestad, M D, assistant secretary, Council on Medical Education and Hospitals of the American Medical Association. Discussant: Reginald Fitz, M D, member, Council on Medical Education and Hospitals of the American Medical Association president, Massachusetts Medical Society
- 4 15 p m "Round Table Discussion on Public Relations." "Co-operative Community Relationships" W W Bauer, M D, director Bureau of Health Education American Medical Association
"The Job of State and County Societies in Medical Public Relations" C Charles Burlingame, M D chairman Committee on Public Education, American Psychiatric Association chairman Committee on Public Relations Connecticut State Medical Society
- 4 45 p m Discussion
- 5 15 p m Adjournment

ALLEN G RICE

MICHAEL A TIGHE

APPENDIX NO 10

REPORT OF A MASSACHUSETTS REPRESENTATIVE TO THE HOUSE OF DELEGATES OF THE AMERICAN MEDICAL ASSOCIATION

As one of your members of the House of Delegates at the meeting of the American Medical Association in Chicago from December 1 to 5, 1945, I have the following report to make:

ea where the tissue was somewhat firmer and noother. The terminal bronchi were not visible, wing to obstructing masses of hemorrhagic tissue. A biopsy of the left lower bronchus showed chronic inflammation. A slight hemoptysis occurred four days later, when an x-ray film showed no change. The patient's condition was unchanged after bronchoscopy.

An operation was performed on the sixteenth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. LOWREY F. DAVENPORT. This patient, if the history is accepted at face value, had had chronic recurrent pleurisy for four years, the last attacks becoming more acute and finally showing what appeared on x-ray examination to be collapse of the left lower lobe. In the differential diagnosis the following factors should be considered: the initial history of trauma, the question of whether there was an underlying tumor, and the possibility that the whole picture could be explained on the basis of chronic infection. Before the implication in the record that all the difficulty was pleural is accepted too readily and since x-ray study was reported as showing the disease to be in the lower lobe, it would be well to see the films — lesions below the diaphragm, causing elevation of the diaphragm and partial compression of the lung, are often misleading. A herniation through the diaphragm may cause obstruction to major bronchi.

DR. MILFORD D. SCHULZ. The films of the chest show an area of increased density occupying the position of the left lower lobe, which seems to be reduced in size. The gas bubble of the stomach rides higher than usual. The left leaf of the diaphragm is not visible, but because of the position of the gas bubble in the stomach I am certain that it is elevated.

DR. DAVENPORT. Are you also certain that there is no evagination of the diaphragm, with abdominal organs in the chest?

DR. SCHULZ. There is nothing to make one think of such a condition. The right lung and the chest elsewhere appear normal. I do not see the tuberculosis that was reported to have been found elsewhere in the chest.

DR. DAVENPORT. On the basis of the symptomatology, which includes no gastrointestinal disturbance in this period of four years and on the basis of the x-ray films, the premise that the lesion was actually above the diaphragm can be accepted. I believe that one can go farther on the basis of this film and rule out any mechanical obstruction due to such a lesion as aneurysm of the aorta, which can block the lower lobe and cause confusing symptomatology. Hilar lymph nodes large enough to cause such obstruction are usually of sufficient size to cause some suspicion in the x-ray films.

Taking all these points in chronologic order in attempting to arrive at a final diagnosis, one should evaluate the onset of the illness and determine whether the abrupt onset four years previously was traumatic enough to explain the whole picture. The presenting symptom when the patient first consulted a physician — the sudden onset of left-sided chest pain while he was at work — suggests the possibility of spontaneous pneumothorax. X-ray films taken at that time, however, failed to disclose any air within the chest and showed only a thickened pleura. The subsequent course, with repeated attacks becoming progressively severer and finally accompanied by infection, is not the picture that is seen with spontaneous pneumothorax. I believe that the persistence of thickened pleura over a period of years means the persistence of some type of infection. A thick pleura is often seen on x-ray examination, particularly in cases of long-standing infection in which the infection, whether pyogenic or tuberculous, finally subsides and the shadow that is called thickened pleura in the x-ray film also clears. The trauma that called the patient's attention to some pre-existing disease four years previously is rather difficult to evaluate, but I believe that trauma can be dismissed as being responsible for the subsequent events.

The question of both benign and malignant tumor must be considered. Some of the most puzzling cases have occurred when the primary difficulty was benign. Adenomas cause bronchial blockage, with suppuration behind such a block. The rule in this type of case, however, is that such patients present evidence of infection, with block behind the tumor mass and subsequent extension of the suppuration into the pleura, so that such a presenting symptom as pleurisy is not usually the initial complaint. Such a possibility, of course, cannot be clearly excluded on the basis of the information that is given in the record, but for the moment will be regarded as unlikely.

So far as malignant tumors are concerned, one is also faced with the four-year history, as well as symptoms that, according to the record, quite clearly began with pleurisy. This raises the question of a pleural endotheoma, a type of cancer that is not accepted as being a frequent neoplasm in the chest. The general opinion is that most cases showing pleural invasion at autopsy have cancer in the bronchus as the original focus. Such cases are reported but are rare in our experience, and a four-year history of a wildly growing pleural endotheoma is most unusual. Malignant tumor of the bronchus must be considered, but is unlikely in view of the fact that the symptoms began four years previously. The periods of as long as a year between attacks are unusual with malignant tumor. The onset and the lack of evidence of suppuration are against the possibility that the initial process was

become eligible for election as president-elect, which happened by unanimous vote

The election of Dr. Fouts to become speaker naturally followed in order because he has been assistant speaker for several years at least. He is a very hard, earnest worker and in my memory the first man from the x-ray field to be elected to that position. The election of Francis F. Borzell, of Philadelphia, to be vice-speaker was an excellent choice. He is another hard working, entirely co-operative man.

Many spoke of the work of James McCann, of Massachusetts, in connection with his work on the principles of the Blue Shield. We are also fortunate, I think, in Joseph Lawrence, who serves as a very good sounding post for the American Medical Association in Washington.

The 1946 meeting will be held in San Francisco from July 1 to 5, the delegates from California spoke of their plans and hopes and felt certain that by that time transportation difficulties would be largely a matter of history, emphasizing the availability of hotels to take care of the number probably coming. The meeting in 1947 is to be held in Atlantic City, and that in 1948 in St. Louis.

The meeting dissolved after three very strenuous days and with a feeling, as I have said above, that almost too much was attempted. But the reason for the attempt I have also stated — the element of uncertainty in Washington.

CASE 32371

PRESENTATION OF CASE

A twenty-four-year-old farmer entered the hospital because of attacks of pleuritic pain.

Four years before admission, while lifting packing cases, the patient had a sudden knifelike pain in the left chest, in the region of the axilla. It was made worse on deep inspiration and on change of position. A physician took x-ray films, which were interpreted as showing pleurisy. There were no chills, fever, cough or general malaise. The chest was strapped, and the pain subsided completely for a year, when an identical attack occurred while the patient was at work. X-ray studies showed a thickened pleura. Three or four days of strapping again gave complete relief for a year, when a third attack occurred, with a temperature of 104°F, which lasted a few hours. A slight cough accompanied the attack, in the course of which he spat up about 30 cc of bright-red blood. An x-ray film taken at a tuberculosis sanatorium was reported as showing a thickened pleura. The fourth and severest attack occurred five months before admission while the patient was driving a truck. Again the temperature rose to 104°F and subsided within a few hours. There was no cough, sputum or hemoptysis. The pain lasted three or four days. X-ray examination at the sanatorium was said to show two or three "spots" of tuberculosis in the lung. Three additional x-ray films at another sanatorium were reported as showing only a thickened pleura. Four months before admission drench-

ing sweats occurred almost every night for three weeks but did not recur. During this acute episode the patient lost 15 pounds, which he rapidly regained on returning to work. During the three months before admission he felt well for several days at a time and then, particularly in poor weather, felt weak, lost his appetite and was forced to go to bed for a few days. These attacks were not accompanied by pleuritic pain or fever. Because of persistent symptoms he consulted another physician, who after fluoroscopy stated that the left lung was "dead" but that the patient did not have tuberculosis and could be cured in ten weeks. No tuberculin test, sputum examination or chest tap had ever been performed. For a few weeks before admission, while the patient was doing heavy work, dyspnea, accompanied by a slight cough productive of a small amount of yellow sputum, occurred for the first time. There had been no known exposure to tuberculosis.

Physical examination revealed a slightly diminished expansion of the left chest. The percussion note was dull over the entire left chest, with diminished breath sounds and loss of tactile and vocal fremitus. No rales were heard.

The temperature was 100.5°F, the pulse 100, and the respirations 20. The blood pressure was 128 systolic, 86 diastolic.

Examination of the blood showed 12.6 gm of hemoglobin and a white-cell count of 11,500, with 67 per cent neutrophils. The urine was normal. The sedimentation rate was 6 mm in fifteen minutes, 24 mm in thirty minutes, 30 mm in forty-five minutes and 33 mm in sixty minutes.

An x-ray film of the chest showed the diaphragm to be high and fixed on the left side. There was extensive density throughout the lower third of the left lung field. The heart shadow was displaced to the left, and the hilus was displaced downward. In the lateral view the density appeared to represent a collapsed left lower lobe.

Bronchoscopy was performed on the fourth hospital day. The lower lobe bronchus was reddened, containing a moderate amount of thin, bloody secretion and some friable tissue that bled easily and was regarded as being possibly inflammatory. On the posterior wall, however, there was one

proved to be active tuberculosis, that point need not disconcert us too much. It must be realized that there may have been a bronchial tumor, with secondary infection in the bronchus, and that the bronchoscopist at the time of examination may have run into inflammatory tissue above the level of tumor. We are told that a biopsy showed only chronic granulation tissue, and there is no definite evidence of sputum studies. The most probable diagnosis must be chosen on a percentage basis. Tuberculosis, being a frequent type of infection, produces an inflammatory picture similar to that reported in this case. I am well aware that without more evidence and more definite studies than were reported in this case the diagnosis may come as a surprise.

DR EDWARD B. BENEDICT: What was your final diagnosis?

DR DAVENPORT: Tuberculosis.

A PHYSICIAN: Do you consider multiple infarcts a possibility?

DR DAVENPORT: Not a likely possibility, in view of the subsequent episodes that were accompanied by sputum and a high temperature.

DR BENEDICT: I bronchoscoped this patient, and my preliminary diagnosis was adenoma of the bronchus. That was based on the fact that he was a young man with a history of repeated hemoptysis and repeated attacks consistent with intermittent bronchial obstruction. When I looked down the bronchus there was one area that had the smooth, firm appearance that is consistent with adenoma. The biopsy report, however, was chronic inflammation so that we were somewhat puzzled, but Dr. Richard Sweet who did the operation decided that resection was indicated, on the basis of x-ray evidence of a collapsed lobe.

CLINICAL DIAGNOSIS

Adenoma of bronchus

DR DAVENPORT'S DIAGNOSIS

Collapse of left lower lobe, due to bronchial obstruction, presumably tuberculous

ANATOMICAL DIAGNOSES

Adenoma of bronchus

Bronchiectasis

Chronic pneumonitis

PATHOLOGICAL DISCUSSION

DR CASTLEMAN: I am sorry that Dr. Sweet is not here. His preoperative note reads, "This man will not really get well until he has a lobectomy." When lobectomy was performed, a small, shrunken, hard, left lower lobe that was completely atelectatic and moderately adherent all around and to the diaphragm as well was found. When I examined

the lobe in the operating room, there was a good-sized tumor in the main left lower bronchus. I could not be absolutely sure whether or not the resected edge contained tumor, but a rapid frozen section from the resected edge revealed tumor typical of a benign adenoma. Dr. Sweet, therefore, took out the upper lobe because the tumor would undoubtedly continue to grow in the bronchial stump that still remained. He had originally resected as much of the lower-lobe bronchus as he could without sacrificing the upper lobe.

When the specimen was examined later there was complete occlusion of the dorsal division bronchus leading to the apex of the lower lobe. About half the tumor was extrinsic to the original tumor in the dorsal branch, the other half having extended through into the posterolateral division bronchus, which was almost completely occluded. The tumor measured 2 cm in its greatest diameter. There were numerous enlarged inflammatory lymph nodes all around this bronchus and all along the trachea. A section through the lung parenchyma itself showed extensive bronchiectasis and pneumonitis.

DR BENEDICT: This is an example of what Dr. Davenport meant when he said that one sometimes finds a great deal of inflammatory tissue around the tumor and that a biopsy is often not diagnostic.

DR ALLAN M. BUTLER: I think that this case is also a good illustration of the importance for a surgeon to decide not to obtain further information but to operate, because operation was indicated no matter what the diagnosis was.

DR CASTLEMAN: The patient had, as the physician said, "a dead lung."

DR ALLEN G. BRAILEY: What was the cause of the pleurisy?

DR CASTLEMAN: Bronchial obstruction produced pneumonitis, followed by pleurisy.

CASE 32372

PRESENTATION OF CASE

A nineteen-year-old unmarried woman entered the hospital because of pain in the lower abdomen.

The patient was apparently well until eight hours before admission, when she awoke with a feeling of indigestion and epigastric discomfort. Shortly thereafter the discomfort shifted downward, and she began to have increasingly severe lower abdominal pain. She also became nauseated and vomited everything eaten. A physician sent her to the hospital after administering morphine and atropin.

The patient began menstruating five years before entry, and the periods had always been normal and regular. The last menstrual period, which had begun two days before entry, was in no way unusual. She persistently denied sexual intercourse or having missed any recent period. She had had

due to a plugging of a bronchus by either a benign or malignant tumor

If one gives little weight to the onset of the symptoms on a traumatic basis and further to the possibility of a benign or malignant tumor, a third possibility remains — namely, infection, which would have to be extremely chronic to last four years and explain the whole picture. The ordinary pyogenic infections can probably be excluded, and yet such infections are often present for a number of years. In such cases the diagnosis is obscure, but the presenting symptoms and subsequent course move more swiftly than those in the case under discussion. So far as infection is concerned, infectious granulomas, such as syphilis, tuberculosis and the obscurer types of fungous infection should be considered. Syphilis of the lung, if one excludes congenital syphilis, is an extreme rarity, and I use that redundancy deliberately. It is consequently rather difficult to tie up any of the symptoms with even the types of syphilis of the lung that are reported in the literature, and such a diagnosis can probably be dismissed.

The infectious granulomas of the fungous type can be confined to actinomycosis, because actinomycosis in this part of the country is the most frequent of the fungous infections and the one that has given the obscurest forms of pulmonary disease for long periods of time. The only clue in the history is the fact that this patient was a farmer, and actinomycosis occurs oftener among the rural than among the urban population. Cases among city workers have recently been seen in this hospital, however. I recall a stenographer some years ago who to the best of her recollection had not even spent her vacation in the country. She had a long history, with x-ray changes suggestive of tuberculosis for a period of years, and not until the chest was opened was the diagnosis of actinomycosis made. There are several points to remember in considering such a possibility. The sulfur granules show up only in accumulations of pus, and it has been our experience that the fungus in the sputum is extraordinarily difficult to identify. There are several considerations against accepting this as a likely diagnosis. First, it is relatively rare in spite of the fact that it is one of the types frequently encountered. Secondly, actinomycosis of any appreciable duration almost always causes draining sinuses in the chest, although cases have been reported in which actinomycosis has been a factor during a period of years without causing the typical draining sinus that is usually associated with this type of disease. A primary pulmonary form of the disease, with secondary pleural involvement, occurs, and most of these cases show hemoptysis, which was noted in the case under discussion.

The laboratory data are meager, and I take it that the statement that there were no examinations

of the sputum and no tuberculin test or chest tap is true, and that no bronchoscopic aspiration was performed.

DR. BENJAMIN CASTLEMAN That is correct.

DR. DAVENPORT We then come to the last and I believe the most difficult diagnosis to consider seriously, accepting the fact that we have a rather obscure history and rather less than the usual data that are furnished in such a case. We do not have a negative blood Wassermann or Hinton test to lean on. Because of the greater incidence of tuberculosis in the population, an atypical form of tuberculosis causing this symptomatology is much more frequent on a percentage basis than a typical form of an obscure type of condition. This is the possibility to which most weight should be given. If the onset four years previously is accepted as being due to infection of the pleura, the recurrent pleurisy is quite consistent with tuberculosis, causing fibrinous and later fibrous adhesions with elevation of the diaphragm. Uncomplicated tuberculous pleural effusion is probably never seen. Most authors believe that even a primary pleural effusion not complicated by parenchymal aspects, as in the case under discussion, is due to some underlying focus of disease in the lung, whether or not demonstrated in the x-ray film. In this case, after four years of repeated attacks of pleurisy, there was increasing evidence of involvement of the left lower lobe, which can be explained on the basis of involvement of the bronchial mucosa by tuberculosis. This condition has become more and more appreciated in the last few years, since it has been looked for and since repeated bronchoscopic examination has been performed. It accounts for the previously obscure localization of active tuberculous disease in the bases, as well as for the fibrotic stenoses with partial obstruction, atelectasis and poorly aerated lower lobes that are the end result of a fibrostenosis due to tuberculosis. The one thing that worries me about the diagnosis of tuberculous pleurisy in addition to associated bronchial tuberculosis is that in my experience such patients have a distressing, continuous cough. In this case, as the record points out, there were long periods during which the patient was free from all pulmonary symptoms. In such a situation sputum is often difficult to obtain, and if the disease is active in the bronchial mucosa there is a certain amount of blockage of the parenchymal disease and the patient may go for a long time without the demonstration of tubercle bacilli on sputum examination. It is somewhat unlikely that the patient was studied in this hospital and in the sanatorium without more emphasis on the sputum examination. I rather expect that if the complete history were known there would be disconcerting evidence that previous sputum examinations performed elsewhere were negative. Since negative examinations have been reported in cases that subsequently

ANATOMICAL DIAGNOSIS

Double intussusception and volvulus of ileum, led by adenomatous polyp.

PATHOLOGICAL DISCUSSION

DR. HERRERA At operation the cystic mass was found to be bowel, with a double intussusception, which in addition had rotated on the mesentery so that the intussusception below it had also formed a volvulus. It was impossible to reduce the intussusception, and since the bowel was obviously gangrenous, resection was carried out with a side-to-side anastomosis.

DR. CASTLEMAN The specimen we received in the laboratory consisted of a double ileoileal

intussusception. We were also unable to reduce the intussusception because of the extensive gangrene and interadherence. By cutting across the bowel, we unraveled the different layers and found that the mass that led the intussusception was an adenomatous polyp, which was almost completely infarcted. The first intussusception, which was about 25 cm in length, in turn had intussuscepted for a distance of 30 cm, so that 60 cm of small bowel was involved in a double intussusception. I believe that this was the youngest patient in the adult series that we have seen. When the condition occurs in children, it is usually not due to tumor.

a slight intermenstrual discharge. The appetite had been good, although she suffered from occasional constipation or transient indigestion. She had had a normal bowel movement on the day of entry. There had been no urinary symptoms.

Physical examination revealed the heart and lungs to be normal, except for a soft systolic murmur, varying somewhat with respiration and heard over the entire precordium, although it was loudest at the apex. The abdomen was soft, and a smooth, firm, slightly tender lower abdominal mass could be felt in the midline, reaching up to the umbilicus. Peristalsis appeared normal although somewhat sluggish. Pelvic examination revealed a narrow introitus, which seemed to be virginal. The cervix was normal to palpation, and no pain was elicited by motion. The fundus was small and could be felt separate from and anterior to the abdominal mass, which had pushed it somewhat to the left. There was some tenderness high in the left vault. The patient was menstruating.

The temperature was 99.4°F, the pulse 100, and the respirations 24. The blood pressure was 130 systolic, 70 diastolic.

Examination of the blood revealed a hemoglobin of 12 gm and a white-cell count of 18,000, with 86 per cent neutrophils. The urine was normal.

An operation was performed.

DIFFERENTIAL DIAGNOSIS

DR GORDON A. DONALDSON. The diagnosis in this case is either quite obvious or extremely obscure, and in keeping with the usual outcome of cases discussed at these exercises I suspect that we had better stick to the most obvious. Certainly the resident in the Emergency Ward who saw this patient believed that the diagnosis was obvious because the studies obtained were minimal. I take it that no x-ray films were made.

Without laboring too many other possible diagnoses, there are one or two features that are worthy of comment. In the first place, if one were looking for a more typical story for an acute inflammation of the appendix, it would be difficult to find even in Zachary Cope's description of typical acute appendicitis. In this case there is the classic type of pain, with the typical shift downward, consistent with the history of eight hours' duration. The nausea and vomiting, which I suspect occurred after the pain, classically in acute appendicitis often precede the pain. This is a minor point, however, the difference probably depending on whether the appendix is mechanically obstructed or diffusely inflamed. A diagnosis of acute appendicitis with appendiceal abscess formation cannot be made, in view of the pelvic and lower abdominal findings. An appendiceal abscess is not likely to reach such proportions in such a short time.

With this history of intestinal obstruction, probably reflex epigastric discomfort and radiation of

pain down into the seat of the disease, one must also think of diseases along the course of the terminal ileum. Could there have been a lesion in a Meckel's diverticulum—perhaps a foreign body? We have recently seen a patient with a huge gallstone in a Meckel's diverticulum that finally led to ulceration and abscess formation. Tumors in this region and intussusception are all inconsistent with the large pelvic and lower abdominal mass. Presumably, this patient had had rheumatic fever, but I cannot tie in such a mass with a diagnosis of rheumatic fever in a patient who eight hours previously had been well. I do not like the reference to the possibility that she was pregnant, I consider the story and physical findings inconsistent with extrauterine pregnancy.

Other possibilities in the region of the pelvis come to mind: hematosalpinx in one tube, presumably the right (but I think that is unlikely), and torsion of a pedunculated fibroid, which had grown during the course of menstrual life. If this was a fibroid it was certainly of tremendous size, and one that is not seen in a patient of this age.

Throughout the physical examination attention is focused on the lower abdominal mass, which evidently lay posterior to the fundus of the uterus, displacing it anteriorly and slightly to the left. It was of such size and weight that it was probably responsible for the pelvic congestion and intermenstrual discharge. This tumor, moreover, had undergone a recent inflammatory change, probably the result of torsion, which accounts for the elevation of the white-cell count and temperature, and was tender to palpation. The most obvious organ involved and the one responsible for this patient's symptoms was the ovary, probably the right ovary, and in a patient of this age the likeliest diagnosis is dermoid cyst.

DR BENJAMIN CASTLEMAN. A cyst that had twisted?

DR DONALDSON. Yes.

DR RODOLFO E. HERRERA. When we saw this patient we also could not help being impressed by the mass in the abdomen, and that was the reason for the lack of additional laboratory and x-ray studies. The mass was easily palpated on abdominal examination, and our preoperative diagnosis was the same as Dr Donaldson's. We examined the pelvis and rectum, both with and without anesthesia, and the only thing that was disturbing about the diagnosis of ovarian cyst was that the mass could not be felt well from below and did not seem to rise from the pelvis. We explained the difficulty simply by saying that it had a long pedicle that had twisted.

CLINICAL DIAGNOSIS

Twisted ovarian cyst.

DR DONALDSON'S DIAGNOSIS

Twisted ovarian dermoid cyst.

the care of the sick has not been made available obviously it is highly desirable to train a certain number of graduate nurses who have had a broad educational background so that they can fill teaching, administrative and supervisory positions. On the other hand, the chief function of a nurse is the bedside care of the patient — a duty that some of the graduates of the modern school of nursing appear path to assume.

The editorial states that the Virginia Board of Nurse Examiners should seek a solution without being influenced too much by sources that insist that most schools should turn out a type of graduate who is able to pass the board examinations of any or all states. It suggests that the Virginia schools immediately convert to a two-year course, with a substantial reduction of the didactic work, and that the large schools, particularly those in teaching centers, should be encouraged to offer postgraduate courses in specialized training for a certain number of these two-year graduates. Undoubtedly two years is an adequate period to train a person in bedside nursing. But, the editorial points out, one of the major objections made by nursing educators is that a two-year graduate is not recognized by the boards of nursing in many states. The answer is simple. If a two-year graduate so desires and has the necessary aptitude, she may continue her education for one or more years and thus become eligible to take the board examinations in the thirty-eight states that now require three years of training, as well as qualify for a teaching, administrative or supervisory position. The advantages of this scheme, as stated in the editorial, are as follows: the shortening of the period of training and the reduction of expense to the pupil would attract larger numbers, one class of nurse of high quality would be continued, better specialists would result from the planned postgraduate courses, and the care of the sick would be restored as the primary duty of the graduate nurse. This seems to be a logical approach to the problem.

The two-year graduate should not be considered as a substitute for the so-called "attendant nurse." The latter should be encouraged but never with the idea of having her take the place of an adequately trained young woman with at least a high-

school education. The attendant nurse has a definite place, particularly in the home, but should not assume those responsibilities in bedside nursing for which she is unqualified by educational background and training. She and the registered nurse with the proposed two-year course of training should be complementary to each other.

By such measures, any state, especially those with a large number of small hospital training schools, should be able to provide enough young women adequately trained in clinical nursing to care for the sick in hospitals and homes. This two-year type of trained nurse does not need (nor would many desire) to be registered in all states. There would however be ample opportunities to provide further educational background for those who are able, willing and suitable for supervisory positions in hospitals, large or small. The trained attendant would take over from both classes of trained nurse many of the routine duties that are time consuming and the performance of which does not require a high-school education — let alone two or more years in a training school for registered nurses. A certain number of two-year graduates, by virtue of postgraduate study, and possibly of advanced preliminary education, would be qualified to assume highly responsible positions. The majority would be capable of rendering excellent bedside care, although they would not be permitted, under existing statutes, to take board examinations in many other states. Finally, the attendant nurse would assume many of the time-consuming routine duties that do not require skilled service.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

CROSBIE — Arthur H. Crosbie, M.D., of Boston, died August 23. He was in his sixty-ninth year.

Dr. Crosbie received his degree from Harvard Medical School in 1903. He was a consulting urologist at the Massachusetts Women's Hospital, Boston, and St. Elizabeth's Hospital, Brighton, and surgeon-in-chief, Department of Urology, Cambridge City Hospital, Cambridge. His memberships included the New England Surgical Society, American Association of Genito-Urinary Surgeons, American Urological Association and American College of Surgeons.

His mother and five brothers survive.

SARGENT — Ara N. Sargent, M.D., of Salem, died August 26. He was in his seventy-ninth year.

Dr. Sargent received his degree from Harvard Medical School in 1893. He was a member of the American College of Physicians and a fellow of the American Medical Association.

MATERIAL should be received not later than noon on Thursday two weeks before date of publication.

THE JOURNAL does not hold itself responsible for statements made by any contributor.

COMMUNICATIONS should be addressed to the *New England Journal of Medicine*, 8 Fenway, Boston 15, Massachusetts.

NEW ENGLAND POSTGRADUATE ASSEMBLY

THE program of the fifth New England Postgraduate Assembly, which will be held on October 30 and 31, appears elsewhere in this issue of the *Journal*. These meetings were inaugurated in 1938, were held through the following three years but were canceled during the war years. Some idea of their popularity and their value as one means of postgraduate medical education may be gained from the fact that in one year the total registration was 925.

As in the past, the Program Committee has arranged for a series of talks by eminent physicians who, by and large, are not residents of New England.

The choice of topics has been excellent and has resulted in a program that should prove to be of interest to all practicing physicians.

There are two innovations. In the first place, the meetings will be held in downtown Boston, — at the Hotel Bradford, — which should appeal to those who plan to stay in Boston during that time. Secondly, there will be a technical exhibit by a number of commercial firms, which should offer an excellent opportunity for all registrants to become acquainted with recently introduced drugs, the latest type of instruments and other material currently available to practicing physicians.

The facts that the majority of medical officers have been discharged from active duty and that civilian physicians have been relieved of a great deal of the pressure under which they worked during the war years should result in a record breaking attendance. It would be difficult to devise a two-day program that would offer more in the way of a means of becoming acquainted with recent advances in diagnosis and treatment.

SHORTAGE OF NURSES

MUCH has appeared recently in the lay press regarding the critical situation created by the shortage of nurses, and the *Journal* commented on it editorially in the July 11 issue. Many reasons have been advanced for the present crisis, but little has been done to remedy it. An editorial, entitled "The Training of the Graduate Nurse," in the July issue of the *Virginia Medical Monthly* suggests an underlying cause that has been present for many years and offers suggestions for its correction.

This editorial maintains that recent trends in nursing education have been largely responsible for the present situation. It is certainly well recognized that, at least in Massachusetts and probably in other states, many of the small nursing schools have been forced to close because they could not meet the increasing educational requirements for the registration of their graduates. In other words, in the attempt to raise the standard of nurses a sufficient proportion of persons who are willing to

TWELVE YEARS' EXPERIENCE IN ROENTGENOTHERAPY FOR CHRONIC ARTHRITIS*

JOHN G. KUHN, M.D.,† AND SIDNEY L. MORRISON, M.D.‡

BOSTON

ROENTGENOTHERAPY as a local treatment to the joints in chronic arthritis was begun by us over twelve years ago. We were prompted to institute this form of treatment after reading the early optimistic reports of Kahlmeter¹ in Sweden and of Scott² in London. At first the treatments were given with great caution. After a number of unexpected successes and an equal number of failures, a general plan of treatment for certain articular lesions in chronic arthritis was developed. During this time we learned to expect certain effects in the joints, and by trial and error we found some of the indications and contraindications to the treatment. By the end of August, 1945, x-ray therapy had been given to 370 selected patients, of whom 252 had rheumatoid arthritis and 118 osteoarthritis. Five hundred and sixteen separate joints were treated, exclusive of spines. In the majority of cases one joint was treated. Although a large number of patients were treated for various types of nonarticular rheumatic disease, such as fibrositis and bursitis, these have not been included in this study.

The articular lesions of chronic arthritis have been treated with x-ray almost from the time of Roentgen's discovery in 1896. In 1897 Sokolow³ published the first report on this treatment, claiming that it gave relief in arthritis deformans. The first American report was made in 1906 by Anders, Daland and Pfahler.⁴ Since the beginning of the century numerous studies have appeared and, almost without exception, have claimed improvement in chronic arthritis following roentgenotherapy. Staunig⁵ reported in 1925 that he had treated 400 patients. In 1933 Langer,⁶ stating that therapy had been beneficial in 200 cases, advocated x-ray treatment to the spinal ganglions, since he believed that one of the main actions was on the sympathetic nervous system. By 1935 2000 arthritic patients had been treated by von

Pannevitz,⁷ who reported improvement in more than 95 per cent. Between 1925 and 1937 Kahlmeter⁸ treated over 5000 patients, although excellent results were claimed; in the entire group, he stated that the best results were seen in the early stages of arthritis. Scott,⁹ who was one of the pioneers in roentgenotherapy for arthritis, in 1939 advocated wide-field x-ray therapy, which he reported to be particularly valuable in rheumatoid arthritis of the spine.

The first carefully controlled study on the effect of roentgenotherapy in chronic arthritis was made in 1941 by Smyth, Freyberg and Peck¹⁰ on 100 unselected patients with various forms of rheumatic disease. They concluded that significant improvement that could be attributed to the therapy occurred in only 14 per cent of patients. Definite relief, however, followed roentgenotherapy in 72 per cent of patients with rheumatoid arthritis of the spine. They believed that much of the improvement reported by earlier writers was largely subjective. In the earlier papers little in the way of statistics or objective data was given. The findings were difficult to evaluate because of confusion of local with systemic changes and of subjective with objective improvement. The suggestive effect of this form of therapy on certain patients is often profound. For this reason subjective impressions must always be viewed with suspicion. The x-rays undoubtedly exert some systemic effect, but such systemic changes are inconstant and usually immeasurable. These varied reports on the value of roentgenotherapy led us to analyze our objective and measurable findings in the treatment of a selected group of patients suffering from chronic arthritis.

METHOD OF TREATMENT

Our technic of treatment was similar to that reported from both European and American clinics. The method varied in different joints, depending on the tissues to be penetrated and on the anatomic area to be covered. As a rule 200 r was given twice a week over two to four target areas for six treat-

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

POSTPONEMENT OF SCHOOL OPENING INADVISABLE

Every year the question comes up Should school opening be delayed because of the incidence of poliomyelitis in the town or in neighboring towns? The Department of Public Health strongly urges that the schools be opened at the usual time and be kept open

There is nothing to be gained by keeping the schools closed Experience shows that spread of the disease is not prevented by any such measure On the other hand, by keeping the schools open the child is under the observation of school physician, nurse and teacher in addition to that of the parents at home In this way the early stages of infection are likelier to be detected, the child being isolated and brought under proper medical supervision Missed cases too frequently result from the unsupervised mingling of children when schools are not in session

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender Books that appear to be of particular interest will be reviewed as space permits Additional information in regard to all listed books will be gladly furnished on request

A Synopsis of Medicine By Sir Henry L Tidy, K B E, M A, M D, B Ch (Oxon), F R C P (Lond), consulting physician to St Thomas's Hospital, London Eighth edition, revised and enlarged 12°, cloth, 1215 pp Baltimore Williams and Wilkins Company, 1945 \$7 50

This standard compendium, first published in 1920, has been thoroughly revised and brought up to date, especially in the field of therapeutics The use of the sulfonamides has been incorporated into the sections on infectious diseases, and the chapter on the hemolytic anemias of the newborn has been rewritten in relation to the Rh factor Many new disease syndromes have been included, and the discussion of other diseases has been amplified Vitamin K is included for the first time, and there is a new article on sex hormones Many articles have been extensively rewritten, resulting in an addition of about forty pages to the text The work is well arranged and, although based on British practice, should prove useful to the practicing physician as a ready source of reference

Lights Out By Baynard Kendrick 8°, cloth, 240 pp New York William Morrow and Company, 1945 \$2 50

This is the story of a blinded soldier and his conditioning in Army hospitals for a normal everyday life

NOTICES

ANNOUNCEMENT

Dr Lendon Snedeker announces his return to the practice of pediatrics at 319 Longwood Avenue, Boston

METROPOLITAN STATE HOSPITAL

The twelfth Postgraduate Seminar in Neurology and Psychiatry will begin Friday, October 11 The program will be as follows A review course in basic neurology and psychiatry, consisting of eighty-one lectures, to be held every Friday from 2:00 to 10:00 p m from October 11 to December 13, 1946, and from January 3 to April 25, 1947, at the Metropolitan State Hospital, 475 Trapelo Road, Waltham, a course in social and special psychiatry, consisting of thirty-six lectures, to be held every Wednesday from 5:30 to 10:00 p m from October 16 to December 11, 1946, and from March 19 to May 14, 1947, at the Boston Psychopathic Hospital, 74 Fenwood Road, Boston, and a course in pediatric neuropsychiatry (child psychiatry), consisting of twenty lectures, to be held every alternate Monday from 5:30 to 10:00 p m from October 14 to December 9, 1946, and from March 17 to May 12, 1947, at the Walter E Fernald State School, Waverley

The seminar is open to all graduate physicians, but the number of vacancies for demonstrations in the review course in basic neurology and psychiatry will be limited to twenty-five in each of the subjects of the course neuroanatomy, neuropathology and neuro-röntgenology Those interested are requested to apply in writing before October 7 to Dr William C Gaebler, superintendent, Massachusetts State Hospital, Waltham

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, SEPTEMBER 19

- FRIDAY, SEPTEMBER 20**
*10:00 a m-12:00 m Medical Staff Rounds, Peter Bent Brigham Hospital
- TUESDAY, SEPTEMBER 24**
12:00 m-1:00 p m Dermatological Service, Grand Rounds, Amphitheater, Dowling Building, Boston City Hospital
*12:15-1:15 p m Clinico-röntgenological Conference, Peter Bent Brigham Hospital
- WEDNESDAY, SEPTEMBER 25**
*10:30-11:30 a m Medical Clinic Isolation Building Amphitheater Children's Hospital
*12:00 m Clinicopathological Conference (Children's Hospital) Amphitheater, Peter Bent Brigham Hospital
*2:30-4:00 p m Combined Clinic by the Medical Surgical and Orthopedic Services Amphitheater, Children's Hospital
- *Open to the medical profession

DIAGNOSIS	TOTAL NO OF CASES	NO CHANGE		SLIGHT IMPROVEMENT		MODERATE IMPROVEMENT		MARKED IMPROVEMENT	
		NO OF CASES	PER-CENTAGE	NO OF CASES	PER-CENTAGE	NO OF CASES	PER-CENTAGE	NO OF CASES	PER-CENTAGE
Rheumatoid arthritis without spondylitis	154	32	20.8	26	16.8	61	39.9	35	22.7
Rheumatoid arthritis of spine	98	15	15.4	34	34.7	37	37.7	12	12.2
Osteoarthritis	118	33	28.0	29	24.5	40	34.0	16	13.5

per cent) and marked in 16 (13.5 per cent). In 6 cases there was complete disappearance of symptoms. There were failures in 33 patients, most of whom had deformities of varying degree, as well as extensive spur formation. Mechanical disalignment, which seems to be more significant in osteoarthritis than in rheumatoid arthritis, continues to produce inflammatory changes in the joint, and little can be expected from local therapy until such disalignment has been at least partially corrected.

The selection of articular lesions for roentgenotherapy comprised about 1 in 12 of the patients receiving treatment on the wards. X-ray treatment was regarded not as a cure for arthritis, but as a helpful local measure in certain cases. The chief indication for roentgenotherapy in rheumatoid arthritis was chronic swelling in a joint that failed to subside after several weeks' rest and physiotherapy. Most of these joints respond to roentgenotherapy if there is no serious deformity or internal derangement. Persistent stiffness and pain were the indications in osteoarthritis, in which decrease in swelling is often difficult to measure and the effect of x-ray therapy seems to be chiefly one of analgesia with an increased range of motion at the joint. In rheumatoid arthritis of the spine, a decreased range of chest expansion and severe muscular spasm, with marked forward bowing of the spine, responded fairly readily to x-ray treatment and permitted earlier and more rapid application of corrective apparatus. Roentgenotherapy after manipulative procedures, which was given only during the last year of the study, seemed to lessen muscular spasm and to prevent the reformation of adhesions, but its action was observed for too short a time to justify a definite statement. None of the cases in which such therapy was used after manipulation were included in this study.

To determine the effect of suggestion on the changes observed, the treatments were given to one

jective improvement was observed in the treated knees in 7 cases. In 3 patients with severe deformity there were no objective changes, and only questionable subjective changes in 1. The psychic effect of roentgenotherapy in such patients therefore does not appear to have been an important factor in the improvement.

Kahlmeter⁵ stated that better results were obtained with roentgenotherapy in the early than in other stages of chronic arthritis. A graph was made

TABLE 3 *The Subjective Effect of Roentgenotherapy*

of all patients suffering from rheumatoid arthritis (Fig 1). Although there is a slight decline of the curve with longer duration of symptoms, the variation from year to year is not great. It is probable that the decrease in improvement was due more to the greater number of severe deformities than to the duration of symptoms per se. With a local treatment like roentgenotherapy the condition of the joint at the time of treatment appeared to be the important factor. A comparison of the different types of chronic arthritis showed no significant variation from the graph for cases of rheumatoid arthritis, except that in osteoarthritis the response showed no relation to the duration of symptoms.

ments, 1200 r in six treatments during a period of three weeks comprised a course of treatment, and no further treatments were given to the patient until at least two months had elapsed. In rheumatoid arthritis of the spine, wide-field therapy in doses of 100 r was applied over two spinal areas, an upper and a lower, every other day for twelve treatments, no further therapy was given for two months. The dosage depended on the stage of the disease and the general condition of the patient.

At first an arthritic inflammation that showed little response to rest and physiotherapy was the only indication for roentgenotherapy. Before long,

tion of the forward bowing of the spine were the most important changes observed. Subjective improvement was recorded by questioning the patient about the amount of pain, how freely motions could be performed and how much stiffness was present.

RESULTS

The results of roentgenotherapy in this selected group of patients are shown in Table 1. In most cases the subjective impressions of change were almost parallel to the objective, and although examination failed to verify the improvement claimed by some patients, the number of such cases was

TABLE 1 *Effect of Roentgenotherapy in 370 Selected Patients with Chronic Arthritis*

BASIS	NO CHANGE		SLIGHT IMPROVEMENT		MODERATE IMPROVEMENT		MARKED IMPROVEMENT	
	NO OF CASES	PER-CENTAGE	NO OF CASES	PER-CENTAGE	NO OF CASES	PER-CENTAGE	NO OF CASES	PER-CENTAGE
Subjective impression	69	18.9	94	25.4	163	44.0	44	11.8
Objective impression	80	21.6	89	24.1	138	37.2	63	17.1

however, it was noticed that certain lesions responded fairly readily to x-ray treatment whereas others did not, and roentgenotherapy was therefore prescribed more carefully. The selected group of 370 patients was about one tenth of the total treated on the wards during the twelve-year period.

Since articular changes occur frequently with exacerbations and remissions in the disease, it is essential that patients be observed during a period in which their condition remains relatively unchanged. In such cases x-ray therapy was used as an adjunct to the general medical and orthopedic measures. The patients were compared with an equal number on the wards at the same time who had similar articular lesions whose treatment differed only in the absence of roentgenotherapy. Only changes in the joints that were more rapid and definite in the patients treated with x-ray were recorded as improved, when the changes were no different in the treated and untreated groups the effect of the roentgenotherapy was recorded as negative.

Objective changes were evaluated by observation, by measurement of the circumference of the joint and by recording the range of active, painless motion. If decrease in swelling and tenderness was little, with a decrease in articular circumference of less than 1.3 cm and with an increased range of active, painless motion no greater than 10°, the improvement was recorded as slight. If the decrease shown by articular circumference was from 1.3 to 2.5 cm and there was an increased range of painless, active motion of from 10 to 30°, improvement was recorded as moderate, the effect beyond this was tabulated as marked. Improvement in the spine, although definite, was more difficult to evaluate. Increase in chest expansion and more rapid correc-

relatively small. Of the 290 cases in which objective changes were observed (78.4 per cent of the series) improvement was slight in 89 (24.1 per cent), moderate in 138 (37.2 per cent) and marked in 63 (17.1 per cent). In only 25 of the patients listed as markedly improved, was there complete subsidence of all inflammation and of all symptoms, a rare effect following roentgenotherapy. In 80 patients, or 21.6 per cent, no improvement could be found, this large percentage of failures was probably due chiefly to a faulty selection of articular lesions. Indiscriminate use of roentgenotherapy in all forms of rheumatic disease gave discouraging results, as Smyth, Freyberg and Peck¹⁰ have shown.

There were considerable variations in the effects of therapy in the different types of chronic arthritis (Table 2). The best results were obtained in rheumatoid arthritis of the spine, in which — as pointed out by Scott,⁹ Hare¹¹ and Smyth, Freyberg and Lampe¹² — there is a more rapid subsidence of muscular spasm and pain, an increase in chest expansion and in spinal movement and a decrease or sometimes a complete disappearance of nerve-root pain. Improvement occurred in 84.6 per cent of the 98 patients with rheumatoid arthritis of the spine. Improvement was slight in 34 (34.7 per cent), moderate in 37 (37.7 per cent) and marked in 12 (12.2 per cent). Twelve patients were completely relieved of symptoms, 15 who were not improved showed marked ankyloses and deformities. In most cases, plaster casts were applied and active exercises were given during or soon after roentgenotherapy, usually with continued improvement. There were only 2 relapses. In rheumatoid arthritis without spondylitis, improvement was seen in 79.5 per cent of 154 patients. Improvement was slight in 26 (16.8 per

hours after the first treatment were not unusual. Exacerbation of symptoms after subsequent treatments must be rare, since none were encountered. Among 21 women treated by roentgenotherapy for rheumatoid arthritis of the spine, menorrhea developed in 2, one of whom was twenty-eight and the other thirty-four years of age; the condition persisted in these patients. In a fifty-year-old man a drop in the white-cell count from 500 to 1800 was observed after three x-ray treatments to the spine. The patient complained of pro-

stressed the value of x-ray treatment in limiting and combating acute infections. Ochsner and Mumford,¹⁶ without explaining its *modus operandi*, found that roentgenotherapy was helpful in relieving pain in lesions of the bones and joints. In chronic arthritis following x-ray treatment Hernaman-Johnson¹⁷ observed local analgesia, absorption of articular exudate, decreased thickness of the articular capsule and increased density of the bone.

In recent biopsy studies following roentgenotherapy to the joints of both dogs and patients suf-

FIGURE 2 Roentgenograms before and after Roentgenotherapy in a Fifty-Year-Old Man. The film on the left was taken before treatment. The film on the right, taken six months later, reveals no significant changes, except for a possible slight increase in osseous density.

found weakness, and the leucopenia was an incidental finding. X-ray treatments were discontinued. Three weeks later the white-cell count returned to 7000. In no other case was any change observed in the blood. The sedimentation rate was not altered in any case, and no significant changes in the results of other laboratory tests were recorded.

DISCUSSION

The effect of x-rays on the tissues of the joint is not fully known. It is generally assumed that the action is almost wholly local, in spite of the early uncritical assumption that systemic changes result. Some of the action is probably destructive of newly formed connective tissue, as suggested by Röhr.¹⁸ Ewing¹⁴ enumerated the following chief effects of x-rays on the tissues: destruction of rapidly proliferating cells, increased permeability of the cell membrane, inhibition of cell ferments, vascular changes, and lymphatic exudation. Desjardins¹⁵

suffering from intermittent hydrops, Horwitz and Dillman¹³ found a disappearance of edema from the tissues and a diffuse fibrous thickening of the vascular walls, with obliteration of the lumens of the small vascular channels. In dogs doses up to 8000 r led to loss of fur and slight superficial ulceration of the skin, but no changes in the joints. In studying the effects of x-rays on growing epiphyses, Spangler¹⁹ and later Barr, Lingley and Gall²⁰ observed that severe damage and, at times, complete necrosis of the epiphyseal cartilage followed irradiation. The latter investigators also found that irradiation amounting to 1335 r or more caused epiphyseal damage in rats, but that no changes were found in the joints. Hatcher²¹ reported the development of sarcoma in 3 patients given roentgen or radium irradiation; in a review of the literature he found that extremely large doses had been given whenever this complication occurred.

The patients in this study demonstrated a diminution in swelling, frequently rapid subsidence of articular exudate, extensive local analgesia and a

Since it had been our clinical impression that a greater and more lasting change was ensured if two or more series of treatments were given to the arthritic joints, two or more series were given in 74 patients. A review of the data revealed that if no change was observed with one series little improvement could be anticipated from further x-ray

FIGURE 1 *Effect of Roentgenotherapy in Rheumatoid Arthritis in Relation to the Duration of the Disease*

therapy. If a fair amount of improvement occurred from one treatment, slightly more effect followed a second one. The results of one and of two or more treatments are presented in Table 4. A greater improvement was noted in patients receiving two

ment in 18 and with no definite cause in 14, of whom 4 had severe nephritis and 2 severe cardiac disease. The failure of therapy in 15 cases of rheumatoid arthritis of the spine was associated with serious deformity and ankylosis in 7, and no cause could be determined in 8, in which severe nephritis was present in 2.

The majority of these failures, which occurred during the first three years of the study, can be attributed chiefly to a faulty selection of patients. In osteoarthritis with severe articular derangement and spur formation, little improvement can be expected from x-ray treatment. If the deformity is first corrected and the joint made mechanically as efficient as possible, roentgenotherapy hastens subsidence of the inflammation and often removes pain. Metastatic cancer is occasionally found in the presence of chronic arthritis and is often not demonstrable by x-ray for many months. Serious systemic disease and infection should not greatly hinder a local treatment like roentgenotherapy, but the experience in this study suggests that they do. The chief cause of failure, however, was some mechanical disturbance that hindered the subsidence of the articular inflammation. Although x-ray treatment has proved its usefulness in selected cases, the technic has not yet reached the stage at which the results are always predictable. The following conditions are regarded as contraindications to roentgenotherapy: quiescent rheumatoid arthritis without joint inflammation, severe deformity or articular

TABLE 4 *The Effect of the Number of Courses of Treatment in Arthritis*

COURSES OF TREATMENT	NO OF CASES	NO CHANGE		SLIGHT IMPROVEMENT		MODERATE IMPROVEMENT		MARKED IMPROVEMENT		RELAPSES	
		NO OF CASES	PER-CENTAGE	NO OF CASES	PER-CENTAGE	NO OF CASES	PER-CENTAGE	NO OF CASES	PER-CENTAGE	NO OF CASES	PER-CENTAGE
One	296	70	23.6	69	23.3	109	36.8	48	16.2	17	5.7
Two or more	74	10	13.5	20	27.0	29	39.2	15	20.3	3	4.0

or more series. About the same number of relapses occurred, with recurrence of the inflammatory changes in the treated joint, in both groups. To date repeated courses of treatment cannot be said to guarantee permanency of the changes that take place. Any relapses usually occurred within three to six months after the completion of the series of treatments.

Of the total of 80 cases in which no improvement resulted from roentgenotherapy the failure of treatment was ascribed to the following factors: in 33 cases of osteoarthritis severe deformity or articular derangement in 17, no apparent cause in 9, metastatic cancer (disclosed on subsequent x-ray examination) in 4, active syphilis (found later) in 2, and active tuberculosis (subsequently discovered) in 1. In 32 patients with rheumatoid arthritis without spondylitis, the failure was associated with severe deformity or articular derange-

ment, and serious chronic disease or systemic infection.

Although no serious harm to the patients or damage to the joints was observed with the dosage given, the following reactions occurred: local pigmentation of the skin, 9 cases (2.1 per cent), nausea and vomiting, 8 spinal cases (8.1 per cent), temporary exacerbation of arthritis, 20 cases (5 per cent), amenorrhea, 2 spinal cases (9.5 per cent), and leukopenia, 1 case (0.2 per cent). It was therefore concluded that x-ray treatment must be given with caution. Pigmentation of the skin after roentgenotherapy varied tremendously in different patients, occurring to a marked degree in only 9.

Such pigmentation gradually disappeared after x-ray treatments were discontinued. Nausea and vomiting were frequent after roentgenotherapy to the lower dorsal and lumbar spine. Exacerbation of symptoms in the joint lasting from twelve to twenty-

child in 24.1, moderate in 37.2 and marked in 17.1 per cent

The effect varied in the various types of chronic arthritis. The greatest improvement (84.6 per cent) as seen in rheumatoid arthritis of the spine. In rheumatoid arthritis without spondylitis, 79.2 per cent of patients improved. In osteoarthritis the least improvement occurred — 7.2 per cent.

Suggestion apparently played little part in the results of therapy. The decrease in subjective symptoms almost paralleled the objective changes.

The duration of symptoms had little effect on the end results. The condition of the joint was the most important factor.

Repeated courses of x-ray treatment do not ensure the permanence of the improvement.

Roentgenotherapy is useful in selected cases, and its chief indications are chronic inflammation in a joint that has not responded to rest and physiotherapy, pain and stiffness in osteoarthritis, and muscular spasm and spinal limitation of motion and pain in rheumatoid arthritis of the spine.

In the 80 patients who showed no response to roentgenotherapy the principal reasons for failure were severe deformity or mechanical derangement of the joint, cancer not found in the first x-ray examination and serious systemic disease.

Unpleasant effects, such as a temporary increase in symptoms after the first treatment and nausea and vomiting, were occasionally seen, but no damage to the skin or articular tissues occurred.

Roentgenotherapy should be regarded as a local treatment only — a helpful adjunct to the medical and orthopedic measures that are usually prescribed.

decrease in muscular spasm followed by an increased range of active, painless motion. In x-ray films taken two months to ten years after roentgenotherapy, no significant changes were observed in the bones. The slight changes in bone density that were found could readily be accounted for by the increased or decreased activity of the patients (Fig 2). X-ray treatment to arthritic joints in 4 children followed four years or more caused no disturbance in growth (Fig 3). No harmful effects on the skin or articular tissues were observed. In

to determine. The local condition of the joint is the chief indication — chronic inflammation or persistent pain and stiffness with no obvious mechanical cause. In rheumatoid arthritis of the spine, with severe bowing of the spine and ankylosis, little improvement follows roentgenotherapy.

X-ray treatment should not be used to the exclusion of other local treatments, but should be considered only a useful adjunct to the usual medical and orthopedic measures. The joints that were not treated with x-ray eventually improved for the most

FIGURE 3 Roentgenograms before and after Roentgenotherapy in a Five-Year-Old Girl. The film on the left, taken before treatment, shows extensive soft-tissue swelling, articular damage, and osteoporosis. That on the right, taken five years later, shows dense bones and no swelling of the soft tissues. Two courses of x-ray treatment had been given. The knee had normal painless motion.

2 patients in whom repeated operations permitted examination of the articular tissues before and after roentgenotherapy no significant changes were seen after a dosage of 1200 r.

The various forms of chronic arthritis are usually regarded as systemic disturbances whose most obvious and severe manifestations are articular lesions. All the evidence at hand suggests that roentgenotherapy is only a local treatment to the affected joints and that its chief use is in patients in whom one or few joints show disability. The spinal joints seem to show the most rapid and definite response to the treatment, which is of little value when severe deformity or articular derangement is present. In such cases the articular inflammation may be caused mechanically by the deformity or the changes within the joint, and it may subside without other treatment when the mechanical disturbance is removed. The seriously ill patient responds slowly to roentgenotherapy — whether this is due to a profound depression of all reparative processes, we are unable

part, but roentgenotherapy hastened the subsidence of symptoms. All that can be expected in selected patients is an acceleration in the process of recovery. The improvement induced by x-rays is not always lasting. 56.2 per cent of patients showed improvement that persisted, without recurrence in the inflammatory process in the joint. We believe that in these cases the natural healing process has continued after improvement was started by the therapy.

The duration of the effect of x-rays apparently varies. In subsequent observation of the 370 patients only 20 showed true relapses, all of which occurred in three to six months after treatment, the average being slightly more than five months.

SUMMARY

In this study of 370 selected patients suffering from chronic arthritis, the improvement that occurred after roentgenotherapy in 78.4 per cent was

The characteristic febrile paroxysms, with associated symptoms and physical findings, occur in delayed primary as well as in recurrent attacks. In Table 1 the incidence of these symptoms and signs is compared in two groups of patients, one of delayed primary attacks and the other of later relapses. Both groups were observed under the same conditions and were treated with the same drug regimens. It is readily apparent that the two groups showed little difference in the incidence of symptoms and physical findings.

Occasionally, however, the recognition of malaria in a delayed primary attack represents a difficult diagnostic problem. In some cases, smears are persistently negative for several days, despite the oc-

currence of febrile paroxysms, with associated symptoms and physical findings, occur in delayed primary as well as in recurrent attacks. In Table 1 the incidence of these symptoms and signs is compared in two groups of patients, one of delayed primary attacks and the other of later relapses. Both groups were observed under the same conditions and were treated with the same drug regimens. It is readily apparent that the two groups showed little difference in the incidence of symptoms and physical findings.

When faced with fever, chills and severe malaise in a patient who exhibits no diagnostic physical findings and has several negative malaria smears, the physician may be tempted to employ sulfonamides or penicillin or to attempt a therapeutic trial with an antimalarial drug. Such temptation should be resisted. Penicillin is of no value in the treatment of malaria, and the sulfonamides and antimalarial drugs can prevent the appearance of malaria parasites and thus make impossible the establishment of a correct diagnosis. It is essential that the diagnosis of malaria be verified by positive blood smears, so that rational treatment can be instituted for the current attack and subsequent attacks can be promptly recognized and properly treated.

TABLE 1 Incidence of Symptoms and Physical Findings in 84 Delayed Primary Attacks and 190 Later Relapses

SYMPTOM OR PHYSICAL FINDING	PERCENTAGE OF DELAYED PRIMARY ATTACKS	PERCENTAGE OF LATER RELAPSES

Herpes simplex	27	21

currence of chills and fever and other commonly associated symptoms. Such cases are often differentiated with difficulty from a variety of bacteremias or septicemias. The presence of leukopenia in malaria is of some help in ruling out streptococcal, pneumococcal or staphylococcal bacteremias, but does not differentiate malaria from typhoid fever, dengue or cases of influenza in which respiratory symptoms are minimal.

Some delayed primary attacks are ushered in by an irregular fever, without chills and with negative malaria smears. In some cases the fever eventually assumes a tertian character, providing a clue to the diagnosis, in others a chill occurs after a few days of remittent fever and is followed by a more intermittent febrile course.

The onset of a delayed primary attack may be marked by severe abdominal pain and tenderness, and by nausea and vomiting. When these symptoms occur before a paroxysm supervenes, they simulate closely an acute abdominal condition, but the presence of a low white-cell count is a guide to the correct diagnosis.

All these variants from the typical vivax attack occur in later relapses, as well as in the delayed primary attack. The absence of a previous history of malaria, however, and the greater incidence of nega-

INTERVAL BETWEEN CESSATION OF SUPPRESSIVE MEDICATION AND ONSET OF DELAYED PRIMARY ATTACK

Information on 101 patients with delayed primary attacks was assembled, to calculate the interval between the time of discontinuance of suppressive medication and the date of onset of the first attack. In 96 cases data on the dosage of quinacrine taken for suppression were available. For purposes of analysis, the patients were divided into three groups—those who had taken the usual 0.7 gm of quinacrine during each week, those who had taken more than 0.7 gm per week, and those who had taken less than 0.7 gm per week (Table 2).

It is clear that despite considerable variations in the suppressive regimens used in the endemic areas, the mean interval to onset of the first attack following the end of suppression in each of the three groups was essentially the same—forty-one days. The range of intervals was also similar in each of the groups, and the standard deviation was nearly identical: 23.3 in the first, 22.9 in the second and 21.3 in the third. Accordingly, one can predict that two thirds of patients who develop delayed primary attacks will do so nineteen to sixty-three days following the discontinuance of suppressive medication. It must be appreciated, however, that in rare cases the delayed primary attack occurs as long as one year after discontinuance of quinacrine suppression.

INITIAL PARASITEMIA

It was pointed out above that malaria smears are frequently negative at the onset of symptoms in

THE DELAYED PRIMARY ATTACK OF VIVAX MALARIA*

CAPTAIN IRVING M LONDON, MC, AUS, CAPTAIN CHARLES A KANE, MC, AUS, CAPTAIN EDMUND F SCHROEDER, MC, AUS, AND MAJOR HARRY MOST, MC, AUS

DURING the war, American troops stationed in areas where malaria is endemic received quina-crine (Atabrine) or quinine for suppression of malaria, the vast majority receiving the former. A great number of these men were completely free of clinical manifestations of the disease throughout the period of suppression, but after the discontinuance of suppressive medication, the first attacks of malaria occurred. Nearly all the first, or delayed primary, attacks were vivax malaria. Falciparum malaria, with few exceptions, is definitively cured by an effective suppressive regimen of quinacrine if medication is continued for three weeks or more after the last possible infection, vivax malaria is not similarly curable.

In vivax malaria, the symptoms and signs of an acute attack can be well controlled by quinacrine or quinine, but the infection is not eradicated and recurs in a great percentage of cases. The failure of the drugs to effect a complete cure of vivax infections is reflected in the occurrence of delayed primary attacks, as well as of later relapses. The delayed primary attack itself may be regarded as the recurrence of an infection acquired earlier under conditions in which the clinical manifestations were suppressed by antimalarial agents. Despite the basically similar nature of delayed primary attacks and later relapses, the former display distinctive features, which are considered in this paper.

The problem of the occurrence of delayed primary attacks in the United States will not disappear with the end of the war. With more extensive use of suppressive medication in endemic areas and with increasingly frequent travel by American residents to and from such areas, a continued, although lower, incidence of delayed primary attacks can be expected.

MATERIAL AND METHODS

All the patients observed in this study were military personnel infected with vivax malaria of Pacific origin. Detailed observations were made in 169 cases of delayed primary attacks and in 486 cases of later relapses. The two groups were studied under the same conditions.

All patients were admitted for special treatment as soon as possible after the onset of the attack. No patient was treated unless the temperature had risen above 100°F and a smear of the peripheral blood was positive for malaria parasites. Antimalarial therapy was begun on the morning following admission. The drugs and dosage schedules were as follows: quinacrine, 2.8 gm in seven days (1.0 gm the first day and 0.1 gm three times a day

for six days), chloroquine (SN 7618)^{1, 2}, 2.0 gm. in seven days (0.8 gm the first day and 0.2 gm daily for six days), 1.0 gm in one day, 0.8 gm in seven days (0.2 gm the first day and 0.1 gm daily for six days), 1.5 gm in four days (0.6 gm the first day and 0.3 gm daily for three days) and 1.5 gm. in three days (0.9 gm the first day and 0.3 gm daily for two days), quinine sulfate, 29.0 gm in four teen days (3.0 gm the first day and 2.0 gm daily for thirteen days), and quinine-plasmochin, 29.0 gm of quinine and 0.84 gm of plasmochin naphtho-ate in fourteen days (the former according to previous schedule, and the latter, 0.02 gm every eight hours). The ratio of delayed primary attacks to later relapses was essentially similar in the various treatment groups.

Daily observations were made of the symptoms of the attack, evidences of toxicity of the drugs used and physical findings.

Counts of malaria parasites in the peripheral blood were done twice daily, in the morning and in the afternoon, until a negative smear was obtained, after which three consecutive negative daily smears were required.[†] The great majority of parasite counts were made by the Earle-Perez³ method, which utilizes a thick blood smear, the rest of the counts were determined by the leukocyte-parasite ratio, in which a white-cell count is performed and the parasite count calculated according to the ratio of parasites to white cells in a thin blood smear. The two procedures gave similar results, although the former is much simpler.

After the completion of treatment, most of these patients were transferred to the convalescent section of the hospital, where they were observed until relapse or for a period of one hundred and twenty days from the last day of treatment. No antimalarial drugs were given during this period, and smears were examined twice weekly. The occurrence of a positive smear in association with a temperature above 100°F was considered a clinical relapse, and such patients were readmitted to the treatment ward for further study and therapy. A positive smear without fever or symptoms was regarded as a parasitemic relapse and in these cases temperature observations were made three times daily and smears were examined daily until negative, if fever supervened, the patient was admitted to the ward with a diagnosis of clinical relapse.

CLINICAL CHARACTERISTICS

Most delayed primary attacks are clinically indistinguishable from later relapses of vivax malaria.

*From the Tropical Disease Section, Moore General Hospital, Swannanoa, North Carolina.

†All counts were performed by the Imported Malaria Studies Laboratory, United States Public Health Service, under the direction of Captain Don E. Eyles.

clearance were studied. Patients with an oral temperature above 100°F were regarded as having fever. Cases in which a temperature above 100°F represented merely the defervescence from the peak of a paroxysm on the first day of treatment were not included. An analysis of the occurrence of fever on the second day of treatment in 150 cases of delayed primary attack and 465 cases of later relapse revealed a significantly higher incidence in the former (27 cases, or 18 per cent) than in the latter (29 cases, or 6 per cent). This higher incidence may have been related to the slower parasite-clearance rate in the delayed primary attacks, as suggested by the fact that of the total of 56 patients with fever on the second day only 4 per cent were found to have negative smears on that day, whereas of 559 patients who were afebrile on the second day, 25 per cent had negative smears.

As measured by the control of fever and parasitemia, the delayed primary attack responded less readily to effective antimalarial therapy than the later relapse.

RELAPSE RATE AND INTERVAL TO RELAPSE

The efficacy of antimalarial therapy is measured not only by its control of the acute attack but also by its effect on the incidence of subsequent relapse and on the length of interval to relapse.

After treatment with one of the antimalarial drug regimens, each patient was observed until the next attack or, if no attack occurred, for one hundred and twenty days after the last day of treatment. The rate and interval to relapse within one hundred and twenty days could thus be established for each group. In view of the differences noted between the response to treatment of acute attacks in delayed primary attacks and that in later relapses, it was of interest to determine whether differences also existed in the relapse rate and the interval to relapse.

The results of such an analysis in cases followed until subsequent relapse or for one hundred and twenty days are presented in Table 4, which does

within the observation period of one hundred and twenty days.

DISCUSSION

The observations presented above indicate that repeated attacks of malaria produce a somewhat altered response to treatment of an acute attack, patients with later relapses showing a diminished sensitivity to the malaria parasite as demonstrated by the higher level of parasite density required to produce symptoms. The greater effectiveness of antimalarial agents in the control of fever and in the clearance of parasites in the later relapses is a further indication that some immunity is developed during the course of recurrent attacks. Such immunity, however, is sufficient neither to diminish the likelihood of a recurrence within one hundred and twenty days after treatment of an attack nor to cause a lengthening of the interval between relapses.

The data on the interval to the delayed primary attack following the end of suppressive medication raise some interesting questions. As pointed out above, the mean interval to the first attack in 101 cases was forty-one days, with a range of three to one hundred and four days. This wide range obtained in patients who received large doses of suppressive quinacrine as well as in those treated with the usual dosage of quinacrine. An adequate concentration of quinacrine in the plasma is necessary to maintain effective suppression of the symptoms of malaria. There is a considerable range in the plasma concentrations of quinacrine achieved on suppressive regimens, and there are corresponding variations in the time required for the concentration to drop to its minimal effective level after the cessation of medication. Such factors probably account for some of the variation in length of intervals to primary attacks, but not for the wide range of intervals observed. Symptoms do not necessarily develop as soon as the quinacrine concentration in the plasma has fallen below the minimal effective level. One of the other factors that possibly determine the interval may be the natural periodicity of recurrent vivax infections.

Many patients who had had several attacks of malaria stated that the attacks recurred at regular intervals, usually every six to eight weeks, and many followed through the course of several recurrences did show such periodicity. If one assumes a normal variation among patients in the length of the periods between attacks and differences in the periodicity of various strains of vivax parasites, the wide range in the intervals to delayed primary attacks becomes understandable.

During the course of suppression there may be recurrent episodes of malarial activity in which the clinical manifestations are not evident so long as the plasma concentration of quinacrine remains at an effective level. When suppression is discontinued

TABLE 4. Relapse Rate and Mean Interval to Relapse Following Treatment of Delayed Primary Attacks and Relapses

TYPE OF ATTACK	NO OF CASES	CLINICAL RELAPSE WITHIN 120 DAYS		MEAN INTERVAL TO RELAPSE <i>days</i>
		NO OF CASES	PER- CENTAGE

21	More than 0.7	10 to 83	39.9

first dose of drug The frequency distribution of initial parasite densities in delayed primary attacks and relapses is presented in Figure 1

It is evident that the level of parasitemia at the onset of an attack is significantly lower in the delayed primary attack than that in the later relapses Fifty-four per cent of the delayed primary cases

FIGURE 1 Initial Parasite Densities in Delayed Primary Attacks and Relapses of Pacific Vivax Malaria

had counts less than 1000 per cubic millimeter, whereas this was true in only 31 per cent of later relapses These findings are in agreement with the clinical impression that the majority of patients in the former group show a greater symptomatic reaction to low parasite concentrations than those in the latter Low parasite concentrations in primary attacks were observed by Eyles and Young,⁴ who

PARASITE CLEARANCE RATE

It has been our experience in the treatment of large numbers of cases of vivax malaria that, on the whole, patients with low parasite counts at the beginning of treatment are more rapidly cleared of parasitemia than those with high initial parasite counts Inasmuch as the initial parasitemia is significantly lower in the delayed primary attacks than in the later relapses, one might expect that cases in the former group would be more rapidly cleared of parasites than those in the latter, the opposite, however, was observed

Table 3 presents a comparison of the rate of parasite clearance in delayed primary attacks and in later relapses The ratio of delayed primary attacks to later relapses was essentially similar in all treatment groups and offset known variations in the rates of parasite clearance by quinine, quinacrine, chloroquine or plasmochin Twenty-four hours after the beginning of treatment, only 17 per cent

TABLE 3 Parasite Clearance in Treatment of Delayed Primary Attacks and Relapses

of delayed primary cases had negative smears, whereas 25 per cent of later relapses were negative This difference is statistically significant (probability 0.029) On subsequent smears the rates of clearance were gradually equalized

CONTROL OF FEVER

The temperature course is a valuable index of the response of a malaria patient to therapy The presence or absence of fever on the second day of treatment was found to be a useful measure of this response

This measure was applied to the cases of delayed primary attack and to those of later relapse in the same treatment groups in which the rates of parasite

QUARTAN MALARIA OCCURRING SUBSEQUENT TO A BLOOD TRANSFUSION*

Report of a Case

WILLIAM J H FISCHER, Jr., M D,† AND CHARLES L YORK, M D ‡

PROVIDENCE, RHODE ISLAND

CASE REPORT

WITH the return of military personnel from areas where malaria is endemic, the problem of post-transfusion malaria is bound to assume greater importance than it has in the past. The following case deserves mention because of several unusual features.

E M., a 40-year-old married woman, was admitted to the Rhode Island Hospital on February 25, 1946, complaining of chills and fever every 3rd day for the last several weeks she had previously been seen at the hospital on September 19, 1945, when she was admitted in shock. At that time she gave a history of vaginal bleeding for 1 week and profuse bleeding for 3 days following self-attempted uterine instrumentation. While in the hospital she received three 500-cc transfusions of stored blood and 1 unit of plasma. With penicillin and supportive treatment she made an uneventful recovery and was discharged on the 10th hospital day. Following her return home she had considerable irregular vaginal bleeding, but she gained weight and strength and was able to do her housework adequately. At about 7:00 p.m. on November 23, after a short period of malaise, she suddenly experienced a severe shaking chill, which lasted about 2 hours. This was followed by severe drenching sweat, backache and headache, which had entirely disappeared by the following morning. On November 26 malaise and a chill, followed by sweating, backache and headache, returned. She was seen by a physician, who was aware of the cause of her recent hospitalization and who gave her one of the sulfonamides—it was estimated that she took about 7 gm daily for 4 days. During the month of December, there was only 1 episode of chill and fever, which occurred about the middle of the month. The febrile episodes began again on January 12 and occurred at irregular intervals throughout the month. The patient had no symptoms during the first week in February but on February 8 there was a recurrence of chills and fever. From that time until 2 days before admission to the hospital, the chills and fever occurred regularly every third day at a time that the patient was able to predict.

There was no family or past history of malaria, tuberculosis, diabetes or cancer. The patient was born in Vermont, where she had lived for about 37 years before moving to Providence, and had never been outside the New England states. Her health had always been good, except for scarlet fever in childhood and an appendectomy and right salpingo-oophorectomy at the age of 14. She had had twelve pregnancies, 8 babies having been delivered at term, with four pregnancies terminated by induced abortion.

Physical examination revealed a rather thin but well developed woman who appeared well. The temperature, pulse and respirations were normal. The blood pressure was 110/70 in each arm. The examination was entirely negative, except that the oral mucous membrane appeared slightly pale. The liver was not palpable and was percussed at the costal margin on deep inspiration. The spleen was not felt.

On the day of admission, x-ray examination of the chest was reported as negative, and the urine was said to contain a trace of albumin and a trace of sugar.

At about 1:00 p.m. on the 2nd hospital day, just as the patient had predicted, she began to have malaise, backache and headache. These symptoms progressed, and the temperature rose, about 2 hours later she was at the height of a moderately severe paroxysm, with an oral temperature of

105°F. A thick blood film, which was taken during the paroxysm and reported as negative for malarial parasites, was later reviewed and showed quartan parasites, *Plasmodium malariae*. Examination of the blood showed a red-cell count of 3,700,000, with a hemoglobin of 12.6 gm, and a white-cell count of 5950, with 74 per cent neutrophils, 20 per cent lymphocytes and 6 per cent monocytes. The parasite density during the paroxysm, as determined from the original blood film by the method of Watson,¹ was 60 organisms per cubic millimeter. The blood urea nitrogen was 7 mg and the blood sugar 77 mg per 100 cc. The blood Hinton reaction and agglutinin tests for typhoid, undulant and typhus fever were negative. A blood culture was sterile. An electrocardiogram was within normal limits. By 7:00 p.m. the patient was much improved, and by the next morning, except for slight weakness, she was entirely free of symptoms.

At 8:30 p.m. on the 4th hospital day blood films revealed a parasite density of 1566 organisms per cubic millimeter. The white-cell count was 4450. Earlier in the day, an intravenous pyelogram had been reported as normal. At 9:30 a.m. on the 5th hospital day the parasite density was 576 organisms per cubic millimeter, and examination of the blood showed a red-cell count of 4,270,000, with a hemoglobin of 11.3 gm, and a white-cell count of 5450 with 48 per cent neutrophils, 49 per cent lymphocytes and 3 per cent monocytes. The urine showed a trace of albumin but no bile and a urobilinogen concentration of 0.65 mg per 100 cc. The blood urea nitrogen was 8 mg, the blood sugar 77 mg, and the blood cholesterol 118 mg per 100 cc, and the icteric index was 4.2.

As expected, in the afternoon, the patient experienced a malarial paroxysm almost identical to the previous one. At what was judged to be the height of this episode the parasite count was 410 organisms per cubic millimeter. Examination of the blood showed a red-cell count of 4,260,000 and a white-cell count of 4500 with 53 per cent neutrophils, 46 per cent lymphocytes and 1 per cent monocytes. At that time a blood volume determination was done with the dye T-1824,² the 10-minute sample method of Gregersen,³ as modified to the use of the Cencophotometer, being used. The dye was injected by means of a calibrated syringe. Hematocrit determinations on venous blood were done in Wintrobe tubes, and plasma protein determinations by the method of Bowman⁴ were performed on the control and dye samples. These determinations were repeated on the 11th hospital day, after 6 days with no fever or symptoms (Table 1). Quinacrine, 0.2 gm by mouth, was begun at 4:00 p.m. It was planned to continue this dosage every 6 hours for five doses for a total of 1 gm. The patient received 1.4 gm in 0.2-gm doses in the succeeding 48 hours. The dosage then was changed to 0.1 gm three times daily for five more days. The total dosage was 2.9 gm.

At 9:00 a.m. on the sixth hospital day, the parasite density was 432 organisms per cubic millimeter, and examination of the blood showed a red-cell count of 3,950,000, with a hemoglobin of 11.5 gm, and a white-cell count of 3600, with 57 per cent neutrophils, 29 per cent lymphocytes, 13 per cent monocytes and 1 per cent eosinophils. The urine contained no bile, and the urobilinogen concentration was 0.4 mg per 100 cc.

At 10:00 a.m. on the 7th hospital day the parasite density was 450 organisms per cubic millimeter, and the white-cell count was 4500.

On the 8th hospital day—the 4th day of quinacrine treatment—no parasites were seen in the thick blood film. Examination of the blood showed a red-cell count of 3,910,000 with a hemoglobin of 11.5 gm, and a white-cell count of 5500, no differential count was done. On the 10th hospital day examination of the blood showed a red-cell count of 4,150,000, with a hemoglobin of 11.5 gm, and a white-cell count of 4200, with 63 per cent neutrophils, 32 per cent lymphocytes, 4 per cent monocytes, and 1 per cent eosino-

and the plasma concentration declines below the effective level, a clinical attack becomes possible. But the time of occurrence may depend on the periodicity of the infection in individual cases and the relation of the last preceding episode of suppressed malarial activity to the date of the last effective quinacrine concentration in the plasma. Thus, if a period of suppressed activity occurs immediately before the end of suppression, the delayed primary attack usually does not follow for another six to eight weeks. If the periodicity is longer, the attack may not occur until as long as one hundred days later. In cases in which the interval to the first attack is even longer, it is possible that one or more periods of subclinical malarial activity occur before a full-blown clinical attack develops. If a period of activity is due immediately after the discontinuance of suppressive medication in a patient who is highly sensitive to the malaria parasite, the delayed primary attack may readily occur within the first week after the end of suppression.

These considerations, although speculative, seem best to explain the wide range of intervals to the first attack observed following cessation of suppression.

SUMMARY

In this study, based on 169 cases of delayed primary attacks and 486 later relapses occurring in military personnel with vivax malaria of Pacific origin, most of the delayed primary attacks were clinically indistinguishable from later relapses. Occasionally, however, such attacks posed problems in diagnosis. Treatment with sulfonamides, penicillin or antimalarial drugs should be withheld until a diagnosis is established. The existence of malaria should be proved by positive blood smears, so that rational treatment can be instituted and subsequent malaria attacks can be promptly recognized and properly treated.

The mean interval between the cessation of suppression and the onset of the delayed primary attack in 101 cases was forty-one days. One can predict that two thirds of delayed primary attacks will occur between approximately the third and the ninth week after the end of suppression.

The parasite concentrations in the peripheral blood were significantly lower at the onset of delayed primary cases than those in later relapses. Accordingly, thick-smear examinations should be made at least twice daily until parasites are found.

The rate of parasite clearance under treatment was somewhat slower in the delayed primary attack than in the later relapse, despite the lower initial parasite counts.

Fever was less readily controlled in the delayed primary attack than in later recurrences.

The incidence of clinical recurrence within one hundred and twenty days after treatment of the acute attack was essentially the same for delayed primary cases and later relapses. The mean interval to relapse was also nearly identical in both groups, as was the distribution of intervals to relapse within the observation period of one hundred and twenty days.

The higher initial parasitemia in later relapses suggests a diminished sensitivity to the malaria parasite. This finding, in addition to the more rapid parasite clearance and control of fever that occur in the treatment of later relapses, indicates the development of some immunity in the course of recurrent vivax malaria infection.

ved in the United States for thirty-two years. The other, who gave a history of malaria in childhood, had lived in Michigan for thirty-six years. Blood smears were examined for malaria on one occasion in both donors, but no parasites were seen.

Sharnoff, Geiger and Seltzer⁶ reported 2 cases of malaria following the transfusion of stored blood. One of them was the quartan type. The 3 donors involved in this case were natives of New Jersey, the British West Indies and Puerto Rico, respectively. Blood samples from these donors were stored eight, two and eight days, respectively. The other case was tertian (vivax) malaria. The donor involved was a Puerto Rican, and the blood had been stored for two days.

With the exception of the case presented above, no cases of malaria subsequent to blood transfusion have been reported from the blood bank of the Rhode Island Hospital, which from May, 1942, to January 1, 1946, supplied blood for about forty-five hundred transfusions.⁷

Of the 3 donors involved in this case, 2 were Italian born. One was a fifty-six-year-old native of Naples, who gave a history of malaria that had been treated with quinine forty years previously. He had subsequently been free of the symptoms of malaria and had lived in New England ever since his immigration thirty years previously. The second donor, a fifty-seven-year-old native of Brindisi, gave a history of malaria treated successfully with quinine forty-six years previously and stated that he had been free of the symptoms of malaria ever since that time and had lived in New England since his immigration ten years later. The third donor, a fifty-five-year-old native of Providence, stated that between the ages of six and thirteen years she had had malaria every summer. These attacks had all been treated with quinine and had not recurred in the last forty-two years.

Thick blood films were examined once in all 3 donors, and twice in 1, but no malarial parasites were seen. The blood used for the transfusions had been stored at a temperature of 6°C for five days in the first donor, seven in the second, and twelve in the third. In this reported case the length of time between the transfusions of blood and the appearance of the clinical symptoms of malaria was sixty-six days.

In the clinical study of this case, two features were of especial interest. The first was that low parasite densities were maintained during the period of study (Fig 1). Kitchen⁸ states that *P. malariae* appears to be more toxic, in relation to parasite density attained, than either *P. vivax* or *P. falciparum*. The second feature was that blood-volume determinations, one made during a paroxysm and another in convalescence six days later, showed no significant alterations in the plasma, blood or circulating erythrocyte volumes (Table 1). Feldman and Murphy⁹ described blood plasma and erythrocyte changes occurring in infections with *P. vivax* and *P. falciparum* that reflect the response of the body to erythrocyte destruction. The absence of significant erythrocyte destruction, owing to the low parasite densities attained, may explain the absence of significant blood-volume changes in the case reported.

SUMMARY

A case of quartan malaria, caused by *Plasmodium malariae*, in a native of New England subsequent to the transfusion of stored blood is reported. The three donors involved gave past histories of malaria forty, thirty-six and forty-two years previously, but blood films failed to reveal malarial parasites.

The course of the illness, the parasite densities attained, the white-cell counts and the response to quinacrine therapy are discussed.

Plasma, total blood and erythrocyte volumes, determined with the dye T-1824, were essentially the same during a paroxysm as during convalescence.

phils. On the 11th hospital day no parasites were seen in the thick blood film. The blood cholesterol was 140 mg per 100 cc, and the icteric index was 3.3. The urine showed a concentration of urobilinogen of 0.1 mg per 100 cc.

At no time during the hospital stay was the spleen palpable, and only once was the liver edge felt at the costal margin on deep inspiration. The patient was discharged on the 14th hospital day, and when seen in follow-up on April 6, she stated that she had had no further symptoms of malaria.

Figure 1 shows the relations of the fever and pulse rate to the parasite densities and the white-cell count and the response to quinacrine treatment.

Rubenstein, Shulman and Merrill⁴ reported 12 cases of malaria occurring subsequent to blood trans-

fusion where insect transmission does not exist or is extremely rare as the known period of latency of the malarial infection, whether or not the donor presents a history of malaria. In the 5 donors in whom the duration of latency of the malarial infection was established, it varied from twelve to twenty-seven years. Not one of these donors had a history of manifest malaria. The duration of latency of infection in 3 donors with a history of malaria could not be stated. One of the 3 had a positive blood film for malaria. The other positive blood film was found in a patient with no history of malaria. In 8 of the

fusion in Massachusetts since 1929. Six cases were reported during the years 1939 to 1944, and at least 9—possibly 10—of the cases were quartan in type. Ten of the 12 donors involved in the study had lived for a period of years in a country where malaria is known to be endemic. In the other 2

cases of quartan malaria reported by these authors, the incubation period varied from twenty-one to one hundred and eleven days, with an average of fifty-two days.

McClure and Lam⁵ reported 2 cases of quartan malaria subsequent to the transfusion of blood that

reasons for the policy of conservatism in the younger group whenever possible.

All patients were kept in bed and received routine nursing care, with the occasional use of codeine and aspirin for relief of pain. Patients who received sulfonamide therapy were given sulfanilamide or sulfadiazine, or both. The daily dosage varied from 3 to 4 gm, along with an alkali—usually sodium bicarbonate—in suitable dosage.

If one assumes that 25 mm in one hour by the Westergren technic is the normal upper limit of the blood sedimentation rate, 131 cases (44 per cent) were above and 166 cases (56 per cent) were below this level on admission to the hospital.

The chief complaints in the entire series were as follows: pelvic pain, 95 per cent, vaginal discharge, 33 per cent, bleeding, 10 per cent, urinary frequency, 10 per cent, and backache, 10 per cent.

To our knowledge, three errors in diagnosis were made, all in cases diagnosed as acute appendicitis that were in fact pelvic inflammatory disease.

The indications for operation in these cases were persistence of masses or of subjective symptoms or both. A prerequisite for operative interference in most cases was a sedimentation rate of 25 mm or less, to give assurance that active infection was not present.

RESULTS OF TREATMENT

The results of the various forms of treatment are presented in Table 1.

In classifying the cases, improvement consisted in relief of symptoms or subsidence of the disease,

In unoperated cases, cure consisted in complete resolution of all obvious disease and disappearance of all symptoms.

Experience indicated that many patients regarded as improved later had recurrences of the disease.

The following are brief summaries of the 2 fatal cases.

CASE 1 A 26-year-old Negress who had had four pregnancies and given birth to 2 children was admitted to the hospital with acute pelvic inflammatory disease and peritonitis. The sedimentation rate varied from 25 to 100 mm. The patient was given transfusions, infusions, sulfathiazole and sulfadiazine. There was an elevation in temperature daily up to 103°F. The patient progressively failed, dying on the 22nd hospital day of peritonitis.

CASE 2 A 26-year-old Negro primipara was admitted to the hospital with septic, incomplete abortion, parametritis and thrombophlebitis of the pelvic veins. The uterus was evacuated with sponge forceps. Seven small blood transfusions, as well as sulfathiazole and sulfanilamide were given. The patient died on the 73rd hospital day of septic pulmonary emboli and abscess formation.

An interesting observation is that over four fifths of the cases in this series of pelvic inflammatory disease occurred in women under thirty-five and more than half in women under twenty-five years of age. This fact suggests that such disease is characteristic of the early part of sexual life.

The use of sulfonamides appeared to have no influence on the average period of hospital stay, which in patients treated with bed rest alone was almost identical with that in patients treated with

PELVIC INFLAMMATORY DISEASE*

A Survey of 300 Consecutive Cases, with Special Reference to Treatment

JOHN E. TRITSCH, M.D.,† IRVING H. SAXE, M.D.,‡ AND EDWARD SCHNEIDER, M.D.§

NEW YORK CITY

THE sulfonamides have become well established as invaluable agents in the treatment of many infective conditions. As a result, the tendency has been to regard the drugs equally effective in any infective state, and they are given routinely by many physicians whenever a febrile inflammatory condition develops.

For some time, we had doubted the value of the sulfonamides in many of the cases of pelvic inflammatory disease under our care at the Metropolitan Hospital. We therefore examined the literature to determine the experience of others in the use of the drugs in such diseases.

As early as 1938, Gillett¹ believed that sulfanilamide was 100 per cent effective in the treatment of acute salpingo-oophoritis without demonstrable inflammatory masses and in recurrent acute salpingo-oophoritis. He conceded, however, that there was little, if any, improvement if adnexal masses were present.

In 1938, Goff² stated that vigorous sulfanilamide therapy within the first two or three days of an acute gonorrheal infection completely aborted the process in most cases, but that a permanent cure did not necessarily follow. He reported that in patients seen late in the course of infection an occasional pelvis cleared up but that in most cases some residual infection remained. He believed that probably 50 per cent of cases eventually required operation—an operative incidence much higher than that in the cases in this study.

In 1941 Williams³ compared the effect of sulfanilamide therapy on 72 patients with acute pelvic inflammatory disease with that obtained in 100 patients treated similarly except that the drug was not given. He concluded that the dramatic results often obtained with sulfanilamide in streptococcal infections and in pneumonia were disappointingly absent. He stated that, if given early, the drug prevented the development of tubal involvement in gonorrheal infection but was of little value once the inflammatory process in the adnexa had become well established.

Barrows and Labate,⁴ in 1943, studied 204 cases of acute salpingitis treated with sulfanilamide and sulfathiazole, of which 71 were primary and

133 acute exacerbations. They found that primary attacks of less than five days' duration were apparently cured after a week of chemotherapy in 70 per cent of the mild and 66 per cent of the moderate cases, with resolution of adnexal masses. Mild and severe cases of longer duration and recurrent cases showed no adequate response.

In a study of pelvic inflammatory disease of specific origin, Miller⁵ asserted that, except for general measures, no treatment of pelvic inflammatory disease gives satisfactory results, chemotherapy being disappointing in infections above the internal cervical os. He also stated that surgery is ultimately necessary in a large proportion of cases of recurrent salpingitis, particularly in public institutions with a large number of Negro patients, and that conservative surgery must frequently be followed by secondary surgery. Acute appendicitis furnished the chief difficulty in differential diagnosis. He concluded that bacteriologic diagnosis, whether by smear or culture, is highly unsatisfactory.

It was thus evident that our opinion was—at least in part—shared by others, and a survey of our own cases at the Metropolitan Hospital was undertaken. It was decided to analyze a large number of consecutive cases of pelvic inflammatory disease without attempting to classify the type of disease or the cause. The patients had two things in common: all had inflammatory disease of the pelvis and all were ill enough to be hospitalized. Some were desperately ill, and 2 died. Some of these patients were treated by bed rest alone, others by bed rest and sulfonamides and still others by bed rest and surgery.

GENERAL CONSIDERATIONS

The youngest patient in the series was thirteen and the oldest fifty-two years of age. One hundred and sixty-seven patients (56 per cent) were under twenty-five, 90 (30 per cent) were between twenty-five and thirty-five, and only 43 (14 per cent) were over thirty-five.

Two hundred and sixteen patients (72 per cent) were Negroes. This was chiefly due to the fact that the district served by the hospital is largely populated by Negroes, but other factors, such as social and economic status, played a definite role. Because of this racial distribution, most of the patients in this series were probably more neglected than the average patient, with a higher morbidity, mortality and need for operation.

phology of the American Medical Association and the other formed by the American Dermatological Association, working in co-operation with the Council on Industrial Health, defined occupational dermatosis as "a pathological condition of the skin for which occupational exposure can be shown to be a major causal or contributory factor"¹ Recognition of the causative factor in an occupational dermatosis is important, since it has a direct bearing on the care of the case and on prevention of recurrence. It is estimated that 65 per cent of all occupational diseases are dermatoses.^{2,3}

Dermatitis in the form known as eczema is by far the most frequent of the occupational dermatoses. Dermatitis is an inflammation of the skin due to internal or external factors, the result of contact, ingestion, inhalation, injection, instillation or some other method of absorption.⁴ The lesions, which are characterized by erythema, edema, papules and vesicles, may progress to simple scaling and desquamation or may become oozing and crusted and then desquamate, they may become secondarily infected with pustules or persist as infiltrated, excoriated, lichenified eruptions that prove resistant to treatment. Any one of the lesions, or any combination, may be present.

Occupational dermatoses are with few exceptions due to external agents. Dermatitis from such causes (dermatitis venenata) is so frequent that it requires classification. This classification considers first the type of agent, second the use of this agent and third the nature of the lesions produced. The second division is of little value because the agent may be employed under continually changing conditions, for example, paraphenylenediamine is extensively used in the manufacture of cosmetics, textiles and garments and in other branches of industry. The third division is also open to criticism because the same agent may produce varying degrees of disease depending on its strength as applied, the area to which it is applied and the method of application — that is, the degree of friction involved and the length of the period of exposure. An example is that of oils that cause folliculitis of the arms or cancer of the scrotum.

In general, the concentration of the irritant, the length of time it is applied and the condition under which exposure occurs serve to differentiate two types of dermatitis venenata — nonsensitization and sensitization. Just where the former ends and the latter begins is often impossible to determine. Nonsensitization dermatitis is caused by an irritant that affects practically all human skins. The irritant may be a mechanical or physical agent or a powerful chemical applied, either deliberately or accidentally, to the skin. The reaction is sudden and explosive. It is characterized by all degrees of inflammation and at times by the destruction of the cutaneous layers and even the subjacent tissues. The causative factor is almost always recognized and known to the patient, hence, recovery is fairly

prompt, for with removal of the cause the eruption heals rapidly with little or no treatment. Eczema, variously known as sensitization dermatitis, contact dermatitis or contact eczema and allergic dermatitis or allergic eczema is an inflammation of the skin due to repeated exposures to substances that are normally innocuous. In this type of disease there is an initial exposure without resulting lesions, but subsequent exposures to even minimal quantities of the substance involved may result in reactions, manifested either at the local site of contact or as a generalized process. Every eczema is a dermatitis, but the converse is not true.

The actual causes of occupational dermatoses include mechanical, physical and chemical agents, flowering plants and their products and biologic agents. The chemical causes are divided into primary irritants and sensitizers.

A primary irritant is defined by the Council on Industrial Health¹ as follows: "When a substance in a given concentration, in a given vehicle and after a given manner and length of exposure produces clinically manifested irritation on the skin of the majority of persons not previously sensitized to that substance, then that substance is a primary irritant under the specified conditions." Primary irritants usually cause dermatitis after the first contact. They are the strong acids, alkalis, certain salts of heavy metals, solvents, essential oils, dye intermediates and some oils and greases.

A sensitizer is a substance that does not necessarily cause demonstrable cutaneous changes on the first contact but may effect such specific changes in the skin that, after five to seven days or more, further contact on the same or other parts of the body causes dermatitis. Sensitizers are chemicals that are innocuous to most skins. Sensitization may occur after a latent period of varying length — from days or weeks to months or even years.⁵ The important sensitizers are resins, plastics, dyes, oils, soaps, accelerators, explosives, insecticides, plants, drugs and cosmetics. Experimentally no agent has been proved to be of value in desensitizing susceptible persons. It has, however, been the experience of one of us (J. G. D.) that in some industries the worker may become more or less resistant to outbreaks from contact with these substances and be able to continue his work, but that if he stops work and then returns to the same exposure, he may have an explosive recurrence of his eruption. Regarding this resistance there is apparent disagreement. Schwartz⁶ has labeled this phenomenon "hardening," which he describes as the disappearance or the failure of reappearance of an allergic contact type of dermatitis in sensitized persons on repeated exposure in industry to the sensitizing chemical.

In plants manufacturing or using synthetic resin varnishes, there is a high incidence of sensitization dermatitis. Incompletely cured or incompletely polymerized resins and byproducts are responsible

bed rest and sulfonamides. Operative treatment lengthened the hospital stay, but this is understandable, in view of the fact that most patients with high sedimentation rates were kept in bed until this evidence of acute inflammation had subsided. The time required for such a lowering of the sedimentation rate varied but was usually a week or ten days. The duration of hospital stay in these cases was on the average eight days longer than that in the cases without operation.

Improvement obtained with bed rest alone when compared with that afforded by bed rest and sulfonamides showed little difference—91 per cent in the former and 89 per cent in the latter. The small number of patients regarded as cured is outstanding evidence of the inadequacy of these methods of treatment. Cure was obtained in 6 per cent of cases both with bed rest alone and with bed rest and sulfonamides. The percentage of cures in the operative cases was higher, sixty-three per cent of patients being improved and 37 per cent cured. There were no deaths in the operative series.

SUMMARY

A group of 297 patients with pelvic inflammatory disease was studied. The incidence of disease

was much greater in the younger than in the older age group, decreasing progressively with age. Pelvic pain and discharge constituted the most frequent chief complaints.

The therapeutic results obtained with bed rest alone and with bed rest with the administration of sulfonamides were practically the same, as determined by the period of hospital stay and the condition of the patient on discharge.

The incidence of surgical interference in the entire series was low (14 per cent) and was progressively lower in the younger age groups.

The percentage of symptomatic and anatomic cures was greater in the patients who were operated on than in those who were not.

MEDICAL PROGRESS

OCCUPATIONAL DERMATOSES

J. G. DOWNING, M.D.,* AND S. J. MESSINA, M.D.†

BOSTON

INDUSTRIAL medicine made remarkable progress as a result of World War I and World War II. Unprepared in 1917, it rapidly learned by trial and error, so that during the last few years of the later conflict, through preparation and research, it was able to maintain pace with the tremendous production of industry in wartime. Early recognition of the problems of health and hygiene contributed in no small part to the splendid industrial achievement in the United States. Prevention of industrial affections, by the control and elimination of hazards, enabled industry to perform almost a miracle, not only with less manpower but also with personnel less physically fit.

The skin received the first onslaught of industrial exposures. Dermatologists, especially those previously trained in industrial dermatology, were overwhelmed with work involving care of workers, inspection of plants and consultations with sanitary

engineers and insurers. The results of their efforts at control and prevention, especially in cutting oil hazards, rapidly became evident. The groundwork and teachings of the various committees for investigation of occupational dermatoses of the Council of Industrial Health of the American Medical Association early produced excellent results. The field work and publications of the Section of Dermatoses Investigation of the United States Public Health Service merit great commendation for its achievement. It is hoped that a vast amount of knowledge and statistics have naturally resulted from these efforts, and that the chemicals designed for human destruction may now be put to the advantage of the human race. Already, lethal gases and radioactive substances have been tried experimentally in the cure of fatal diseases such as leukemia and Hodgkin's disease.

Occupational dermatoses include injuries, inflammations, burns, stigmas and growths of the skin caused by occupational contact. Two committees, one appointed by the Section of Dermatology and

Already, lethal gases and radioactive substances have been tried experimentally in the cure of fatal diseases such as leukemia and Hodgkin's disease.

Occupational dermatoses include injuries, inflammations, burns, stigmas and growths of the skin caused by occupational contact. Two committees, one appointed by the Section of Dermatology and

*Professor of dermatology, Boston University School of Medicine and Tufts College Medical School.
†Instructor in dermatology, Boston University School of Medicine.

Syphilology of the American Medical Association and the other formed by the American Dermatological Association, working in co-operation with the Council on Industrial Health, defined occupational dermatosis as "a pathological condition of the skin for which occupational exposure can be shown to be a major causal or contributory factor"¹ Recognition of the causative factor in an occupational dermatosis is important, since it has a direct bearing on the care of the case and on prevention of recurrence It is estimated that 65 per cent of all occupational diseases are dermatoses^{2, 3}

Dermatitis in the form known as eczema is by far the most frequent of the occupational dermatoses Dermatitis is an inflammation of the skin due to internal or external factors, the result of contact, ingestion, inhalation, injection, instillation or some other method of absorption⁴ The lesions, which are characterized by erythema, edema, papules and vesicles, may progress to simple scaling and desquamation or may become oozing and crusted and then desquamate, they may become secondarily infected with pustules or persist as infiltrated, excoriated, lichenified eruptions that prove resistant to treatment Any one of the lesions, or any combination, may be present

Occupational dermatoses are with few exceptions due to external agents Dermatitis from such causes (dermatitis venenata) is so frequent that it requires classification This classification considers first the type of agent, second the use of this agent and third the nature of the lesions produced The second division is of little value because the agent may be employed under continually changing conditions, for example, paraphenylenediamine is extensively used in the manufacture of cosmetics, textiles and garments and in other branches of industry The third division is also open to criticism because the same agent may produce varying degrees of disease depending on its strength as applied, the area to which it is applied and the method of application — that is, the degree of friction involved and the length of the period of exposure An example is that of oils that cause folliculitis of the arms or cancer of the scrotum

In general, the concentration of the irritant, the length of time it is applied and the condition under which exposure occurs serve to differentiate two types of dermatitis venenata — nonsensitization and sensitization Just where the former ends and the latter begins is often impossible to determine Nonsensitization dermatitis is caused by an irritant that affects practically all human skins The irritant may be a mechanical or physical agent or a powerful chemical applied, either deliberately or accidentally, to the skin The reaction is sudden and explosive. It is characterized by all degrees of inflammation and at times by the destruction of the cutaneous layers and even the subjacent tissues The causative factor is almost always recognized and known to the patient, hence, recovery is fairly

prompt, for with removal of the cause the eruption heals rapidly with little or no treatment Eczema, variously known as sensitization dermatitis, contact dermatitis or contact eczema and allergic dermatitis or allergic eczema is an inflammation of the skin due to repeated exposures to substances that are normally innocuous In this type of disease there is an initial exposure without resulting lesions, but subsequent exposures to even minimal quantities of the substance involved may result in reactions, manifested either at the local site of contact or as a generalized process Every eczema is a dermatitis, but the converse is not true

The actual causes of occupational dermatoses include mechanical, physical and chemical agents, flowering plants and their products and biologic agents The chemical causes are divided into primary irritants and sensitizers

A primary irritant is defined by the Council on Industrial Health¹ as follows "When a substance in a given concentration, in a given vehicle and after a given manner and length of exposure produces clinically manifested irritation on the skin of the majority of persons not previously sensitized to that substance, then that substance is a primary irritant under the specified conditions" Primary irritants usually cause dermatitis after the first contact They are the strong acids, alkalis, certain salts of heavy metals, solvents, essential oils, dye intermediates and some oils and greases

A sensitizer is a substance that does not necessarily cause demonstrable cutaneous changes on the first contact but may effect such specific changes in the skin that, after five to seven days or more, further contact on the same or other parts of the body causes dermatitis Sensitizers are chemicals that are innocuous to most skins Sensitization may occur after a latent period of varying length — from days or weeks to months or even years⁵ The important sensitizers are resins, plastics, dyes, oils, soaps, accelerators, explosives, insecticides, plants, drugs and cosmetics Experimentally no agent has been proved to be of value in desensitizing susceptible persons It has, however, been the experience of one of us (J G D) that in some industries the worker may become more or less resistant to outbreaks from contact with these substances and be able to continue his work, but that if he stops work and then returns to the same exposure, he may have an explosive recurrence of his eruption Regarding this resistance there is apparent disagreement Schwartz⁶ has labeled this phenomenon "hardening," which he describes as the disappearance or the failure of reappearance of an allergic contact type of dermatitis in sensitized persons on repeated exposure in industry to the sensitizing chemical

In plants manufacturing or using synthetic resin varnishes, there is a high incidence of sensitization dermatitis Incompletely cured or incompletely polymerized resins and byproducts are responsible

for the eruption. Patch tests made with this material on workers suffering from dermatitis or who had an eruption due to contact with the synthetic resins elicited positive reactions. Other workers who were free from any skin eruption but who had previously had a sensitization dermatitis gave negative reactions.

Among workers with tetryl, 56 (11 per cent) of 500 employes in one plant developed dermatitis. In another 1905 (30 per cent) of 6364 workers developed dermatitis, and 1618 (85 per cent) of them returned to work with no further trouble. In a plant manufacturing TNT (trinitrotoluol), 10 per cent of the workers developed dermatitis, and all were able to return to work.⁴ Probst and his associates,⁵ on the other hand, found that tetryl workers did not develop tolerance. In aircraft workers suffering eruptions from dural, aluminum or zinc chromate primer, Hall⁷ encountered no tolerance.

Hardening may be permanent but usually disappears if exposure is discontinued for any length of time. The degree of hardening varies. Exposures to higher concentrations of the sensitizing agent than that to which tolerance has been established may cause a recurrence of the dermatitis.

No attempt is made to present a complete review of all the causes of occupational dermatoses, since only the literature of the last few years is covered. Many causes are so well known and have been so completely eliminated from industry — for example, arsenic in the wallpaper industry — that the subject matter has been divided not according to occupation but according to the offending agent. A brief description of the occupations employing the particular irritant and of the cutaneous reactions to it follows.

MECHANICAL AND PHYSICAL AGENTS

Vibrating Tools

Gurdjian and Walker⁸ reported the occurrence of a circulatory disturbance of the hands of 6 women who used pneumatic hammers. After a few months to several years of exposure to the vibrations, the patients noted attacks of blanching and numbness of the fingers. In right-handed persons, the little, ring, middle and, sometimes, the index finger of the left hand and the tips of the fingers of the right hand were involved. The vibrating tool was held in the left hand, so that in left-handed persons the condition of the hands was reversed. The attacks of blanching often occurred during work, but usually came early in the morning or during washing, especially in cold weather. The condition is known by various names — dead fingers, white fingers, Raynaud's disease and traumatic vasospastic syndrome.

Hunter and Perry⁹ observed white fingers in riveters, caulkers and fettlers using vibrating tools. Telford, McCann and MacCormack¹⁰ reported "dead hands" in users of vibrating tools. Thirty-four cases

developed after six to forty months' use of high speed vibrating tools. These authors recommend that workers who have handled such tools for nine months stop this type of work.

The industries employing pneumatic hammers, high-speed vibrating tools (those operating at 2000 to 3000 r.p.m.), chisels, riveters, road drills and pounding and lasting machines are mining, quarrying, road-making, shipbuilding and shoemaking establishments, locomotive and other work shops and airplane factories. This condition is also said to occur in telephone operators,⁸ but not in our observation of numerous operators.

Glass Fiber

Champeix¹¹ reports mechanical irritation from glass fiber. Manifestations consisted of cutaneous erythema with pruritus, blepharitis and rhinopharyngeal irritation. In the weaving of glass fiber, the dust is not so much harmful as annoying because of the almost incessant itching.

In the manufacture of camouflage nets,¹² cutaneous reactions to spun glass (fiber glass or glass wool) appeared in a group of women handling it. The reactions observed were itching, without demonstrable lesions, and folliculitis. Spun glass is composed of fine threads that float in the air like dust and adhere readily to the skin.

Asbestos Materials

Workers handling asbestos materials — especially amosite, a natural form of asbestos — develop painful warts or corns.¹³ Of 167 workers, 99 presented one or more lesions. Those affected feel a small, splinterlike foreign body in the tips of the fingers, extraction of which is usually unsuccessful. In less than two weeks, a small cornlike tumor appears at the site of injury. This lesion grows slowly and is tender to pressure. When cornification is pronounced, small corns appear on the fingertips and knuckles.

Klauder and Hardy¹⁴ report similar lesions in pipe coverers who handle asbestos with ungloved hands. Workers call this lesion an asbestos corn or wart. The lesion represents a foreign-body reaction to spicules of asbestos that penetrate the skin.

Chlorinated Hydrocarbons

The eruption caused by the chlorinated waxes — chlorinated naphthalene, diphenyl and diphenyl oxide — is called chloracne or cable rash. Differentiation of this eruption and that seen in ordinary acne vulgaris is done by obtaining a history of exposure to the hydrocarbon in question and by finding acneform lesions in areas behind the ears and on the nape of the neck, the buttocks, thighs, knees, abdomen and lower back. These sites are not involved in acne vulgaris.

In a navy yard, over 200 cases of chloracne were observed.¹⁵ The incidence of this rash has increased

because of the great acceleration of the shipbuilding program. Workers come in contact with water-proofed, fireproofed cable impregnated with chlorinated naphthalene, chlorinated diphenyl or chlorinated diphenyl oxide.

Folliculitis was caused by chlorinated hydrocarbons in 5 of a series of 1113 cases of cutaneous disease reported by Klauder¹⁶ in 1943. In an additional 1184 cases reported by Klauder and Hardy¹⁴ 3 cases were chloracne.

The lesions in chloracne are due to chloro compounds deposited as fine particles or condensations on the skin from fumes and solutions.¹⁷ Such compounds plug the follicular orifices and by their keratogenous action cause the formation of comedones. Yellow cysts develop as a result of mechanical plugging of the openings of the glands and the actual keratinization of their walls. Preventive measures in general are the proper selection of workers, cleanliness, the wearing of clean clothing and adequate ventilation. Workers with a tendency to seborrhea or acne should be excluded from this type of work, since they are as a rule more susceptible than others to acneform eruptions.

Cutting Oils

The cutting oils are the most frequent cause of dermatoses in factories engaged in the making and machining of metal parts. In the manufacture of the actual materials for airplanes, tanks, guns and vehicles this vexing problem confronts the industrial physician.

There are two large groups of cutting oils, the soluble and the insoluble. The former consists of a mixture of sulfonated mineral oil and soap containing resin, sulfonic acids and preservatives — phenol, creosol or nitrobenzene — when animal or vegetable fats are used in the oils. These oils are mixed with water and allowed to flow continuously over the material under operation. Their chief function is the cooling of the metal parts. The insoluble oils are mixtures of mineral, animal and vegetable oils, sulfur and chlorine. The last two chemicals enable deeper cuts to be made into the metal without harming the cutting tools. In the oils containing animal or vegetable oils, inhibitors such as phenolic amines are added to prevent rancidity.

Mineral oils cause defatting of the skin. The small amount of animal or vegetable oils present tends to counteract this effect. The cutting oils produce lesions of the skin owing to mechanical interference with or plugging of the pores. Dermatitis, both sensitization and nonsensitization, irritations, abrasions due to metal shivers in the oils and secondary infections are caused by cutting oils. For the sake of simplicity the skin manifestations of these oils are mentioned under this heading.

In a group of 450 cases of occupational dermatosis reported as to cause, 45 (8.5 per cent) were due to petroleum products.¹⁸ Thirty-six cases were of the

oil folliculitis type. There were 1 case each of generalized melanosis, localized melanosis, keratosis and epithelioma and 7 cases of nonsensitization dermatitis from cutting oils. Oil folliculitis was the most frequent form of dermatosis in workers exposed to lubricating oils and greases and was severe in most cases.

Klauder¹⁶ examined 128 men operating automatic screw machines and found comedones, small follicular, hornv papules, acnelike papules, pustules, pyoderma and scars resulting from destruction of the follicular orifices. In only 19 per cent of the workers were no lesions found. In another study of 50 cases of folliculoses,¹⁴ 42 were found to be caused by mineral oil in machine operators and men engaged in quenching metals. Two of these cases were complicated by cellulitis and lymphangitis.

Peck¹⁷ reports that dermatitis from cutting oils, especially those of the insoluble type, occurs more frequently than any other occupational skin disease. The lesions oftenest seen are folliculitis and comedones on the hairy portions of the arms and the anterior surfaces of the thighs.

Schwartz,^{18, 19} after making a survey of the various skin hazards in war industries, reports that cutting oils are frequent causes of dermatitis. They defat and irritate the skin and plug the pores. The sulfur, chlorine or rancid animal or vegetable fats in the oils are irritating. Phenols, creosols, nitrobenzene and other inhibitors present in the oils may sensitize the skin, and steel shivers in dirty oils often cut the skin.

Allergic eczemas are the least frequent types of cutting-oil dermatitis.

Some mineral oils have keratogenic properties and cause papillomas and warts. Schwartz¹⁸ found these lesions in 10 per cent of the workers, an exceedingly high percentage that does not correspond with the observation of others. Certain oils are carcinogenic, but fortunately the mineral oils of North America are low in the carcinogenic scale. Some cases of skin cancer, however, occur in the United States as the result of contact with mineral oil. There was 1 case of epithelioma in 45 cases of dermatosis due to petroleum products.¹⁸

Prevention consists essentially in reducing to a minimum the contact between workers and irritants. Machines should be kept free from grease and dirt by daily cleaning. Oil should not be allowed to accumulate on the floor. Guards should be attached to machines to prevent oil from splashing on workers. Adequate washing facilities and clean work clothes should be provided, and impervious sleeves and aprons should be worn. Klauder¹⁶ advises the use of two protective ointments, the first being

smear thickly over the entire forearm as a base for the second. These ointments are composed as follows:

FIRST OINTMENT		SECOND OINTMENT	
	gm		gm or cc
Zinc oxide	25	Ethyl cellulose	5
White petrolatum	25	Mastic	8
Kaolin	50	Castor oil	1
		Acetone (technical)	86

The second solution is applied with a small brush and dries, leaving a film that is repellent to both water and oil.

Abrasions, Cuts, Friction and Pressure

Abrasions, lacerations and fissures often occur throughout the fish industry, and subsequent infections are frequent and disabling.²⁰ Metal slivers in the cutting oils produce cuts of the skin.¹⁸

Stigmas peculiar to certain occupations are due to pressure, friction, repeated injuries and joint deformities. Ronchese²¹ enumerates the following trades with their stigmas. Stone chisellers have a characteristic large, soft, rubbery callus at the proximal end of the left little finger. Painters and paperhangers have an elongated callus in the center of each shin, owing to pressure of the rung of the ladder. Jewelers, engravers, ringmakers and stone setters show a characteristic large, heavy callus in the center of the right palm, produced by their most important tool, the plier. Mechanics, machinists and toolmakers as a rule have rough hands showing cuts and abrasions. The nails are worn down, the fingertips are often raw, and the palms are studded with metal slivers from handling and filing metal parts. Foundry workers and melters of metals show a vivid-red discoloration (erythema ab igne) of the forearm, which is continuously exposed to intense dry heat in the act of pulling metals from ovens. The shins of junk collectors, garbage men, truck drivers and railroad conductors show varying degrees of abrasions, cuts, scars and pigmentation. This condition is due to frequent trauma to the shins.

Perhaps the most important physical agent of this era from the point of view of health is radioactive material. Its effect on human tissue has merited and will continue to merit careful consideration. In a nonindustrial paper Dunlap²² presents an excellent review of the injuries resulting from roentgen rays and radioactive substances. Years ago industrial physicians learned the deleterious effects of the alpha and beta rays emanating from radium on the health of persons who swallowed or inhaled radioactive substances or took them into their bodies in other ways. Physicists have succeeded in rendering practically all the known elements temporarily radioactive by exposing them on a precursor to the enormous energies generated by the cyclotron. Thus a new industrial hazard is incurred by persons work-

ing with or near cyclotrons or their radioactive products.

The character of tissue damage appears to be identical with the injuries resulting from exposure to roentgen rays or radium. In the manufacture of roentgen-ray tubes there is an obvious hazard to employees for which in most factories there is adequate protection. Detection of flaws in metal castings and welds by roentgenograms and radium photography requires the use of enormous doses of radiation, from which serious effects result if there is no intelligent medical supervision. Insurers in Boston learned this several years ago when an efficiency expert introduced an x-ray machine to speed up a certain process, with resulting radio-dermatoses to workers exposed. The manufacturers of luminous dials have learned the terrible toll among their workers from inexperience in handling minute amounts of radioactive material. The manufacture and handling of radium applicators and needles involve exposure not only to radiations but also to radon gas in the atmosphere and to the chance in halation or ingestion of particles of radium. The mining and handling of radioactive ores should be closely supervised. Although no medical difficulties have been encountered among the miners of pitchblende, the chief source of radium, workers in the cobalt mines of Germany suffered for centuries from an obscure disease of the lungs, recently identified as cancer, that was probably due to inhaled radon gas. Chemists who have worked with radium and related compounds have suffered from burns and anemias. Human curiosity and careless supervision of roentgen-ray equipment, especially the fluoroscope, may be disastrous. A number of workmen in a large industrial plant on the West Coast were seriously burned in a recent series of laymen's experiments conducted with a fluoroscopic machine in the first-aid room.²²

FLOWERING PLANTS AND THEIR PRODUCTS

Woods and Weeds

Piorkowski,²³ observing that dermatitis is frequent among workers handling tropical woods, reported 5 cases in Indians handling mvule wood, which is similar to teak and oak in its uses. The clinical picture was that of an acute dermatitis venenata covering the exposed parts of the face, neck, forearms and hands and causing severe itching. The eyelids were swollen. In 1 case catarrhal conjunctivitis and rhinitis were present. In 4 cases the onset was sudden and the attack lasted for one or two weeks, in another it lasted for six months. The eruption developed subsequently and consisted of chronic eczematous changes, marked pruritus and lichenification. The chemical agents responsible are the alkaloids or nonsaturated resinous acids.

Howell²⁴ in a recent article on contact dermatitis reports that in the Southwest an eczematous contact dermatitis from sensitization to vegetation is a

frequent occurrence. The condition is an occupational hazard among ranchers, farmers and workers in the oil fields. Howell reported 35 patients who were sensitive to weeds — some to several and others to only one. This was brought out by patch tests with the oleoresins of forty-five different weeds.

Extracts and Resins

Cashew-nut-shell oil. The oil of the cashew nut shell is obtained either by roasting the shells, the general practice in India, or by solvent extraction, which is said to produce a much higher yield of oil. The oil is a mixture of 90 per cent monohydric phenol (anacardic acid) and 10 per cent polyhydric phenol (cardol). The cardol fraction is believed to contain the major irritant properties of this oil and is related chemically to urushiol, the irritant principle of poison ivy. Cashew-nut-shell oil has been proved to be a primary irritant and a sensitizer.²⁵ Two patients had to be hospitalized as a result of patch testing with this substance. The oil would be invaluable in industry except for these deleterious properties.

An investigation²⁶ of the manufacture and use of this liquid was conducted when occupational dermatitis due to resinous varnish made from cashew-nut-shell oil and formaldehyde occurred among many workers handling electric components insulated with this varnish. One plant visited had been using cashew-nut-shell oil for nineteen years, manufacturing a variety of resins including insulating varnish, dusts for brake linings, molding powders and millable rubbery compounds. These materials represent products of cashew-nut-shell oil and other chemicals in various stages of polymerization and condensation or cure. In this plant 4 of every 10 new workers handling the raw oil develop dermatitis, and one quarter of the attacks are severe. Patch tests with this oil on 15 subjects showed marked reactions at the end of twenty-four hours in all subjects, which proves that it is a primary skin irritant. Cured varnish caused a positive patch-test reaction in only 1 case.

Lockey²⁷ reports contact dermatitis as developing in 9 men who for some time had been using so-called "H varnish E 107," which contains cashew-nut-shell liquid as one of its main bases. Patch tests revealed that all these men were sensitive to the oil, 7 reacted to the varnish from the barrel that was being used at the time the dermatitis appeared, whereas none reacted to varnish used previously. It is probable that the oil had not been properly broken down in the manufacturing process.

Resins. Over twenty-six hundred objects used in this country are made of resins.²⁸ The phenol formaldehyde and urea formaldehyde resins account for many cases of contact dermatitis during the process of their manufacture. Dermatitis appeared in 78 of 150 workers engaged in making tubes for launching rocket bombs from airplanes, these tubes

were made from paper glued together with a low-polymerized phenol formaldehyde resin.²⁹

Cranch³⁰ states that the outstanding source of trouble in the use of plastics is local — that is, dermatitis. The finished products made from plastics are seldom irritants, and in only a few cases do they cause sensitization with resulting dermatitis.

Hall,⁷ in analyzing occupational dermatitis among aircraft workers, found that those using zinc primer reacted to zinc chromate or to the resins in the primer (phenol formaldehyde, a natural resin and a phtholic anhydride) or to both. Of those who reacted to the primer, 13 per cent were sensitive to one or more of the resins but not to the zinc chromate, and 15 per cent were sensitive to one or more of the resins and also to zinc chromate.

The dermatitis due to resins was uniform in its characteristics. The eyelids were affected in all cases, and the side of the upper two thirds of the neck and the cubital fossas in the great majority. The hand and fingers were affected in only 1 case, and the wrists and forearms in only 6. The average duration of exposure before onset of symptoms was seven months — less than that for zinc chromate. In 3 cases, however, the average duration was less than a week.

Lemon-grass oil. Mendelsohn³¹ reports dermatitis in 8 machinists, carpenters and riggers who worked for three weeks on a ship recently arrived from India. Part of the cargo comprised tanks of lemon-grass oil, some of which was spilled. The cutaneous lesions appeared six to eighteen days after this work. The eruption consisted of discrete and confluent erythematous patches of various sizes, some slightly vesicular. The lesions were on the face, on the flexor aspects of the lower two thirds of the forearms and about the ankles. Three men had edema of the eyelids, and 1 also had considerable dermatitis of the penis, scrotum and upper part of the thighs. Two men reported that members of their families had similar rashes, evidently following contact with their contaminated work clothes. Four workers were patch tested with pieces of pine wood soaked in lemon-grass oil, and all showed strongly positive reactions. Lemon-grass oil has many uses, it is employed in the manufacture of perfume and ionene and as an adulterant for lemon oil.

Fruits and vegetables. In the picking, packing and canning of fruits, various forms of cutaneous irritation are encountered.³² In the citrus fruit industry, dermatitis is caused by the irritant oil in the rind of lemons, oranges, limes and grapefruit. Among the pickers of such fruits, dermatitis is produced by the thorns on citrus trees and by the insecticides and fumigicides sprayed on them. Paronychia occurs among canners of these fruits. Pineapple peelers develop dermatitis from the sharp spears on the fruit, and the high sugar content of

pineapples also causes dermatitis. The sharp fuzz on peaches is irritating to pickers and canners, and the sugar in the juice is also irritating to the skin.

Dierker³³ reports the results of an investigation of dermatitis occurring in a small plant producing marmalades and jellies. No skin irritation was encountered among the workers until a load of Seville oranges was converted into marmalade. The oranges were washed and dried, the skins were removed, and the fruit was cut up. In this operation 5 of 10 workers developed diffuse erythema of the dorsum of the hands and wrists and the webs of the fingers. Patch tests on 8 normal subjects with extracts of the orange skins as well as juice from the fruit elicited no reaction. The workers with dermatitis were not tested. The patch tests, however, gave evidence that no primary irritant was the cause of the dermatitis. It was thought that the high acidity of this species of orange, together with the continuous wetting of the hands, produced the dermatitis. The use of a protective cream against acid, dipping the hands in a weak solution of sodium bicarbonate and the wearing of gloves prevented further trouble.

Peck³⁴ reported dermatitis arising from the dehydration of potatoes. He inspected six plants engaged in this process, only one of which used lye in the peeling process. The potatoes were washed, precooked, immersed in a 10 per cent lye solution and peeled by friction in a rotating drum. The final washing removed all traces of lye. In the other five plants the potatoes were precooked and peeled by rough rubber rolls, no lye being used. After peeling the potatoes were brought to the trimming tables by moving belts, where workers trimmed off the remnants of the peel with special knives, their hands were constantly wet with water and potato juice in this operation. Dermatitis of the hands, which occurred in 24 women workers, started in the hand holding the potato in the trimming operation, it consisted of redness, scaling and sometimes vesicles in the web spaces, resembling *erosio interdigitalis blastomycetica* as the condition progressed. Patch tests with slices of potato, cooked and uncooked, on 12 workers and 5 controls were negative.

This dermatitis is due to long exposure to water and potato juice, which results in maceration of the skin. Workers whose hands are thus constantly wet eventually develop dermatitis and show interdigital maceration and redness suggestive of *erosio interdigitalis blastomycetica*. Patch tests are unnecessary, for no such test can reproduce the occupational exposure. The workers affected include dishwashers, salad makers, vegetable salesmen, cooks, peelers and canners of vegetables and young housewives—by far the largest group encountered in the private practice of one of us (JGD).

Dermatitis occurred in 17 women who worked with carrots.³⁵ The cutaneous eruption appeared on the palms, the thenar and hypothenar eminences, the dorsum of the hands and forearms and in some cases even the neck, face and eyelids. The incubation period was generally from seven to ten days but sometimes lasted for several months. When workers were removed from contact with either cooked or uncooked carrots, the dermatitis cleared up. Patch tests with carrots, cooked and uncooked, indicated that they were definitely the cause of the eruption.

Thirteen women handling partially decayed parsnips for three or four weeks developed dermatitis.³⁶ When the parsnips were cut, the juice ran down the back of the left hand and sometimes down the knife to the right hand. On exposure to the sun, redness, swelling and then pigmentation developed at these sites. Six other women similarly exposed were not affected.

(To be concluded)

MASSACHUSETTS MEDICAL SOCIETY

PROCEEDINGS OF THE ONE HUNDRED AND SIXTY-FIFTH ANNIVERSARY

May 21, 22, and 23, 1946

THE one hundred and sixty-fifth anniversary of the Massachusetts Medical Society was observed in Boston on Tuesday, Wednesday and Thursday, May 21, 22 and 23, 1946, at the Hotel Statler

Seventeen hundred and fifty physicians were registered

TUESDAY, MAY 21

The first scientific session began at 2:00 p m At 5:00 p m the supervising censors met in Parlor D The Cotting Supper was served to 185 councilors in Parlors A and B The annual meeting of the Council was held in the Georgian Room at 7:00 p m There were 191 councilors in attendance

WEDNESDAY, MAY 22

The second scientific session was held under the joint co-chairmanship of Dr W Jason Mixer and Dr C J E Kichham The attendance varied from 500 to 600

The one hundred and sixty-fifth annual meeting of the Society was held at 11:00 a m in the Georgian Room Dr Reginald Fitz presided The attendance was 500 Dr Fitz spoke at length on "The State of the Society" The Annual Oration, entitled "Gastric Surgery," was delivered by Dr Frank H Lahey The annual luncheon was served in Parlors A, B and C to 219 fellows

The third scientific session was held in the Georgian Room from 2:00 to 4:00 p m under the co-chairmanship of Dr Elmer S Bagnall and Dr John Fallon The attendance was 600 The Shattuck Lecture was delivered at 4:00 p m by Dr John B Youmans, whose subject was "Nutrition and the War" (This lecture appeared in the June 13 issue of the *Journal*)

The annual dinner was held in the Georgian Room at 7:00 p m with 525 in attendance The principal speakers were Dr Roger I Lee, president of the American Medical Association, and Dr Elmer S Bagnall, former president of the Massachusetts Medical Society

THURSDAY, MAY 23

A general scientific session began at 9:00 a m and continued until noon under the co-chairmanship of Dr Archibald McK Fraser and Dr Arthur J Gorman The attendance was between 550 and 600

From noon until 2:00 p m a series of section meetings and luncheons was held The Section of Medicine, under the chairmanship of Dr Albert A Hornor, met in Parlor B Fifty-one sat down to luncheon The Section of Surgery, under the chairmanship of Dr Charles F Twomey, met in the Salle Moderne The attendance was 133 The Section of Pediatrics, under the chairmanship of Dr Floyd R. Smith, met at the Junior League, Zero Marlborough Street The attendance was 55 The Section of Obstetrics and Gynecology met in Parlor A, under the chairmanship of Dr Arthur F G Edgelow The attendance was 52 The Section of Radiology, under the chairmanship of Dr George Levene, met in Room 400 The attendance was 28 The Section of Physical Medicine, under the chairmanship of Dr Arthur L Watkins, met in Parlors D and E The attendance was 12 The Section of Dermatology, under the chairmanship of Dr Bernard Appel, met in the Hancock Room The attendance was 38 The Section of Anesthesiology, under the chairmanship of Dr Sidney C Wiggan, met in Parlor C The attendance was 29

From 2:00 to 5:00 p.m a general scientific session was held in the Georgian Room under the co-chairmanship of Dr Frank R Ober and Dr Harry Blotner The attendance was 600

There were seventeen scientific exhibits and eighty-four technical exhibits

The motion pictures, as usual, attracted a large number

The special list of officers, standing and special committees, councilors, censors, admissions and deaths are appended

MICHAEL A TIGHE, *Secretary*

ANNUAL MEETING OF THE SOCIETY

The one hundred and sixty-fifth annual meeting of the Massachusetts Medical Society was called to order by the president, Dr. Reginald Fitz, in the Georgian Room of the Hotel Statler, Boston, at 11:00 a. m., May 22, 1946. There were approximately 500 Fellows present.

The Secretary submitted the record of the last annual meeting held on May 23, 1944, as published in the *New England Journal of Medicine*, issue of August 3, 1944. It was moved and seconded that the record be adopted. It was so ordered by vote of the fellows.

The Secretary reported that the membership of the Massachusetts Medical Society, as of May 23, 1945, was 5786 and as of May 22, 1946, 5989. He said that 85 fellows had died, 16 had resigned and 6 had been deprived of membership. He added that 302 new fellows had been admitted and that 8 had been reinstated. It was regularly moved and seconded that the Secretary's report be accepted.

It was so ordered by vote of the fellows.

At the request of the President, the Vice-President, Dr. W. Jason Mixter, assumed the chair. Dr. Mixter spoke as follows:

Members of the Society, I should like to take a short moment to make a personal report on the activities of your president during the past year. You will find in his report that the condition of the Society is healthy. I am sure that one of the major reasons for this condition is the fact that Dr. Fitz has given lavishly of his time and energy to the business of the Society. He has used tact where tact was needed. He has used the authority of his office for the benefit of the Society where it was needed, and I feel that the Society owes a very large vote of thanks to Dr. Fitz for his activities as our president. Mr. President, I ask you to give your report on "The State of the Society."

Dr. Fitz responded as follows:

For the third time in the last hundred years the Society, on the occasion of its annual meeting, is in a period of readjustment following a great war.

In 1865, the finish of the War between the States was so close that the fellows scarcely as yet realized the full impact of peace. This meeting was poorly attended—in part because of the disturbed state of the Nation and in part because the American Medical Association was to assemble in Boston during the following week. There was no annual dinner, nor did the scientific program lay any great emphasis on war medicine. It is interesting, however, that the most debated topic under discussion by the American Medical Association dealt with specialists: what a specialist was, and what he was supposed to do.

At the annual meeting in 1919, military medicine received much more consideration. Nearly a third of the doctors in Massachusetts had experienced active military service, they seemed eager to resume their civilian occupations as promptly as they could but were equally willing to hear what the war had added to medical knowledge. The *Proceedings of the Council*, on the other hand, do not suggest that any very vital problems had developed, and indeed, except for one instance, the entire meeting was largely devoid of extraordinary contributions. It was at the annual dinner that Dr. Samuel B. Woodward, who was president, presented ideas not often mentioned. These ripened slowly with time and still promise important results. He said that all fellows should take a more active interest than heretofore in legislative matters and should have no reluctance in stating their opinions at the State House or anywhere else on matters concerning the health and welfare of their fellow citizens.

The past year has been an eventful one. As in 1919, approximately a third of our physicians have recently experienced active military service, and as in 1865, the matter of specialization is of vital interest.

A preview, obtained by questionnaires from the American Medical Association, suggested that a new type of practice might presently become manifest. The men in service wrote that they hoped, on discharge, for an urban type of practice rather than for a general practice in rural districts and that they looked forward to opportunities for postgraduate education with the idea of becoming specialists or of working in well organized groups. The Society realized these trends and, through the Postwar Planning Committee, arranged for appropriate steps to assist in their development, should these be necessary.

Our work in postgraduate education is an important milestone. By using available facilities all over the Commonwealth, we have administered, successfully, a variety of postgraduate courses, which have proved both popular and refreshing. More than a thousand doctors have had opportunity to bring themselves up to date on current medical ideas through expertly delivered lectures. In the words of the first Dr. John Warren, the result is that the Society has gone farther than ever before, for the benefit of its fellows, "to promote medical and surgical knowledge by encouraging a free intercourse with the Gentlemen of the Faculty."

The Society has watched the return of its medical officers with care as well as with pride. Apparently the majority of our veterans are as eager as were their older brothers to resume civilian work where they left it and as promptly as they could, up to the present time, they have made no significant attempt either to overspecialize or to overexpand group practices. To be sure, many young veterans are hoping to complete the program of training on which they had embarked before they entered military service. For these men, especially, the Bureau of Clinical Information fills a useful function. Opportunities for the supervised, long-continued type of hospital training demanded by specialty boards are, by necessity, limited. The Bureau of Clinical Information has kept track of such opportunities as there are, and the Postwar Planning Committee has endeavored to create new ones locally. A number of veterans, however, have been disappointed by their inability to find at once exactly the residencies that they hoped would be available. All that can be said is that the machinery of the Society is working to help such men as best it can.

The Postwar Loan Fund represents another attempt by the Society to assist returning veterans. The problems that face a man who has been out of civilian circulation for a few years are bewildering, not only in matters of education but also in the more earthy ones of finding a house in which to live or an office in which to practice or equipment with which to work. For these latter details, the Postwar Loan Fund is of assistance at least it may provide a much-needed sense of financial security.

Our executive work has continued to go forward through usual channels. As Dr. Lee pointed out two years ago, the Society operates through committees. During the past year, twenty-seven committees have functioned industriously on our behalf. It is the President's privilege to be present at all committee meetings that he desires to attend, and thereby he is given unequalled opportunity to keep abreast of the Society's activities.

Most of these committees have functioned with zeal far beyond the ordinary call of duty. I have already mentioned the educational accomplishments of the Postwar Planning Committee. This committee, through a subcommittee established to work in co-operation with subcommittees from the committees on Legislation and Public Relations, also struggled with a hydra that made its appearance at the end of World War I.

At the annual meeting in 1919, there was talk of the physical imperfections in the youth of America that had become manifest through examinations for the draft. This general subject gradually attained national popularity through one or another of its many heads until finally President Truman's National Health Program of 1946 emerged. The opinion of the Society on a matter so important to the nation was crystallized by these subcommittees, by their parent committees and finally by the Council, in the form of a short pamphlet. Herein the Massachusetts Medical

society offers certain basic principles to govern proper medical-care plans and expresses its views concerning national legislation now pending. This is an important document, interesting, chiefly, because it sets forth basic principles concerning the care of sick people to which the majority of fellows wish to subscribe, and interesting, also, because it shows so clearly the Society's philosophy. We wish everyone to have every known essential preventive, diagnostic and curative medical service of high quality. We believe that this can be best attained by a gradual process of evolution rather than by sudden revolution. We believe that it is the responsibility of persons who are able to do so to procure for themselves many phases of medical care by direct payment or by voluntary insurance against their costs. And finally, we continue to cherish an old ideal to receive the best kind of medical care we are convinced that every patient must have the right to select the physician or hospital to which he chooses to entrust the care of his health.

The activities of the Committee on Legislation are perennial. The Society has come a long way since Dr Woodward reminded us of our obligations as citizens. Fellows are less diffident than they used to be at hearings or indeed at meeting legislators as men to men. Several district societies have entertained their representatives or senators at dinner—an important method of breaking down existing barriers, members of the Great and General Court prove agreeable dinner companions, appearing fully as eager as we are to improve the health and welfare of our citizens and willing to hear our views.

The Committee on Legislation has experimented with a new method of organization. During the past year it has functioned through an executive committee and through subcommittees. In this manner each member of the committee has been kept informed of legislative matters in general and each subcommittee has worked intensively on such bills as were assigned it. One subcommittee, for example, studied, with particular care, antivivisection bills, another bills concerned with hospital staff appointments, and a third, the chiropractic bill. The Executive Committee has integrated the work of its subcommittees with the work of the parent committee, drawing heavily on Mr Charles Dunn for legal and technical advice. This method of organization seems reasonable, promises to yield good results and warrants further exploration.

Several months ago, Major General Paul R. Hawley requested the Society to appoint a committee to confer with his office about the medical care of veterans. The Council authorized the appointment of such a committee, which in turn worked most industriously. As a result it is hoped that certain veterans may be free, in case of need, to employ civilian physicians and hospitals of their own choice in Massachusetts. Their hospital expenses will be met through the Blue Cross as agent, and their professional bills will be met through the Blue Shield as agent, according to a fee schedule established to cover almost all professional services that can be offered. The construction of so comprehensive a fee table proved a difficult, time-consuming task, requiring the welding together of many different opinions from various groups of physicians, in its final form it represents, to a high degree, conscientious and painstaking effort.

At its stated meeting in October, the Council voted to blaze a new trail. The committees on Legislation, Postwar planning and Public Relations submitted a joint resolution advocating the creation of a new position in the Society—that of director of medical information and education. The need for a full-time worker in our executive offices had become increasingly apparent for several years, although the definition of the exact duties of such a person was more difficult. The Council supported the resolution offered by these committees and voted to appoint a special committee to nominate a suitable candidate for the new post. This committee as yet has made no nomination, preferring to act slowly on a matter of such importance, the establishment of this position is certain to have far-reaching results.

At the stated meeting in February, the Council made another departure from old ways. It advocated a plan whereby certain licensed physicians in Massachusetts who were graduates of unrecognized medical schools might obtain hospital privileges. This action represents a broad-

minded attitude in the treatment of an old sore point. Everyone knows that Massachusetts, in the past, has licensed a number of physicians who graduated from unrecognized medical schools, and that by last year's legislative action their future source of supply was jugulated. On the other hand, such doctors, already licensed, will continue to practice and are the family physicians of many patients. Dr H. Quimby Gallupe, of Middlesex South, to aid these men and their patients, presented an ingenious plan by which courtesy-staff hospital privileges under carefully supervised regulations could be made more generally available to them. The Council adopted the plan, and the Committee to Meet with the Massachusetts Hospital Association has been assigned the duty of furthering it. Already a series of meetings with hospital representatives has commenced at which the details of the plan will be discussed around a small table with the informality that is possible when small groups are involved. This is an important step. If both hospitals and fellows co-operate to activate this plan, the Society will be able to take credit for having promoted a liberal and unselfish program primarily designed for public benefit but also having substantial educational value.

Twenty-five years ago, the *New England Journal of Medicine* became owned by the Society and subsequently has been published by it. We have been wise in our choice of editors. Dr Walter P. Bowers laid the foundation for the *Journal's* present success and Dr Robert N. Nye has continued to carry forward his aims. During 1945, about 18,000 readers received the *Journal* each week, and the enthusiasm with which our published articles and editorials have been received all over the world is indeed flattering.

I have selected these few features in the Society's most recent history to emphasize how, little by little, our influence and interests expand. In spite of so much exertion our physical condition is satisfactory. Our membership increases steadily, our finances are in good order, and our spirit is that of ardent youth tempered by our recorded age.

Each president, as he discusses the state of the Society at the annual meeting, by necessity renders his report with mixed feelings of pride and humility. For all his days he must remain proud that his colleagues have paid him the compliment of allowing him to occupy the highest office in the Society for a year. On the other hand, he is humble because he realizes how small a part he has played even for those few months, in carrying on the efforts of so large an organization as the Society has grown to be.

The district societies, the Council, the committees with their devoted chairmen, Robert N. Nye, of the *Journal*, Robert St. B. Boyd, the executive secretary, Miss Cowles, tireless in keeping our records straight, Eliot Huhhard, Jr., ever watchful of our purse and, above all, Michael Tighe, tolerant and wise, are our flag-bearers. They are the ones who keep our ideals viable and continue to make Dr Jacob Bigelow's words of a century ago so timely: "I give you, gentlemen, the Massachusetts Medical Society, old but not infirm, numerous but not divided. May it long continue to be what hitherto it always has been the protection and pride of those who are worthy to be its members."

The President resumed the Chair. At the direction of the President, the Secretary read the following amendment to the by-laws:

The by-laws of the Massachusetts Medical Society are hereby amended by adding a new chapter, to be known as Chapter X. The chapter shall read as follows:

Any provision or provisions of these by-laws may be temporarily waived, provided such waiver is not in conflict with the laws of the Commonwealth, provided the provision or provisions sought to be waived are clearly designated, provided the period during which such waived provision or provisions are to continue be definitely stated, provided notice of the proposed waiver accompany the call of the annual meeting and provided the members present at such an annual meeting unanimously consent.

The President explained that this amendment was legally before the Society for action. It had been

approved by the Council and had accompanied the notice of the annual meeting. Its intent, he continued, was to make the by-laws more flexible. The Secretary moved the adoption of the amendment. This motion was seconded and was so ordered by vote of the fellows.

Dr Thomas A Foster, delegate from the Maine Medical Association, was introduced. He responded as follows:

Mr President and members of the Massachusetts Medical Society, the Maine Medical Association and the Massachusetts Medical Society have had a long and friendly relation, the Maine Medical Association being born in 1820, when Maine became separated from the Commonwealth of Massachusetts. During that time we have sent many delegates to the annual meetings of the Massachusetts Medical Society.

With the permission of your president I should like to read some extracts from the report of a delegate to a meeting of the Massachusetts Medical Society, Thomas Albert Foster, of Portland, in 1871:

At twelve noon a meeting was holden in Lowell Institute at which several essays were read by young men who, from the character of their papers, I judge, will make their mark in the profession of medicine in that city. One of them, Dr Fitz I think they called him, I was told had recently returned from Germany where he had been spending some time under the instruction of Professor Burkhardt. His essay was on tuberculosis and was an able declaration.

The delegate speaks at length of other parts of the meeting and made a conclusion that I am not altogether sure is courteous.

As a whole, I think the Massachusetts Medical Society, although having among its members many of the ablest physicians and surgeons of the Country, is very far behind our own association in point of work. As good as the papers were, the subjects upon which they were written were by no means exhausted by their authors and still there was no discussion of any interest upon any of them. I am sure I can return to the Maine Medical

Association and find they still have the ablest physicians and surgeons and their papers are thoroughly prepared and exhausted. The discussion was enlightening.

The President read the list of officers elected by the Council on May 21, 1946.

Dr Fitz then introduced the incoming president, Dr Dwight O'Hara. Dr O'Hara responded as follows:

President Fitz and fellows of the Society, I told the Council last night that my main endeavor will be to continue as nearly as I can to following in the performance and pattern of the administration that Dr Fitz has set up during the past year. I know that I shall not attain his efficiency, but I shall endeavor to do so and I shall count on your support therein. Thank you.

Dr Fitz then introduced Dr Edward P Bagge, the president-elect. Dr Bagge responded as follows:

Mr President and fellows, this is indeed a historic occasion. I believe that I am the first pediatrician who has been put in line for the presidency. I shall try to live up to all the good beginnings that pediatricians are trained in and let the chips fall where they may. I hope that I shall not disappoint the electors.

At this point in the meeting the President introduced Dr Frank H Lahey, who presented the Annual Oration. His subject was "Gastric Surgery." The address was brilliantly given. It held the close attention of the audience through its entire delivery. (The oration appeared in the June 20 issue of the *Journal*.)

Dr Fitz declared the one hundred and sixty-fifth annual meeting of the Massachusetts Medical Society adjourned at 1 00 p m.

MICHAEL A TIGHE, Secretary

APPENDIX

OFFICERS FOR 1946-1947

PRESIDENT Dwight O'Hara, Waltham Office, Boston (15), 416 Huntington Avenue
 PRESIDENT-ELECT Edward P Bagge, Holyoke, 207 Elm Street
 VICE-PRESIDENT Isaac S F Dodd, Pittsfield, 34 Fenn Street
 SECRETARY Michael A Tighe, Lowell Office, Boston (15), 8 Fenway
 TREASURER Eliot Hubbard, Jr, Cambridge, 29 Highland Street
 ASSISTANT TREASURER Norman A Welch, West Roxbury Office, Boston (15), 520 Commonwealth Avenue
 ORATOR Leland S McKittick, Boston (16), 205 Beacon Street

COMMITTEES ELECTED BY THE DISTRICTS

Executive Committee of the Council — Established 1941 (members *ex-officio* and one councilor and alternate elected by the councilors of each district medical society)
 PRESIDENT Dwight O'Hara, Waltham Office, Boston (15), 416 Huntington Avenue.
 PRESIDENT-ELECT Edward P Bagge, Holyoke, 207 Elm Street
 VICE-PRESIDENT Isaac S F Dodd, Pittsfield, 34 Fenn Street.
 SECRETARY Michael A Tighe, Lowell Office, Boston (15), 8 Fenway
 TREASURER Eliot Hubbard, Jr, Cambridge, 29 Highland Street.

Term Expires 1947

BERKSHIRE Isaac S F Dodd, Pittsfield, 34 Fenn Street. (Alternate Clement F Kernan, Pittsfield, 184 North Street)

FRANKLIN John E Moran, Greenfield, 31 Federal Street. (Alternate Frank A Millett, Greenfield, 40 High Street.)
 HAMPSHIRE William A R Chapin, Springfield, 121 Chestnut Street. (Alternate Archibald J Douglas, Westfield, 3 Court Street.)
 MIDDLESEX NORTH William F Ryan, Lowell, 219 Centre Street. (Alternate Walter L Twarog, Lowell, 11 Durant Street.)
 NORFOLK Charles J Kickham, Brookline Office, Boston (15), 508 Commonwealth Avenue. (Alternate Henry M Emmons, Boston, 354 Commonwealth Avenue.)
 WORCESTER NORTH C Bertram Gay, Fitchburg, 62 Day Street. (Alternate John J Curley, Leominster, 89 West Street.)

Term Expires 1948

ESSEX SOUTH Walter G Phippen, Salem, 31 Chestnut Street. (Alternate None.)
 HAMPSHIRE Henry A Tadgell, Belchertown, Belchertown State School. (Alternate Lawrence N Durgin, Amherst, 66 Amity Street.)
 MIDDLESEX SOUTH Harold G Giddings, Newton Centre Office, Boston (16), 270 Commonwealth Avenue. (Alternate Arthur M Jackson, Everett [49], 512 Broadway.)
 NORFOLK SOUTH Daniel B Reardon, Quincy (69), 1186 Hancock Street. (Alternate Nahum R Pillsbury, South Braintree [85], Norfolk County Hospital.)
 SUFFOLK Alexander J A Campbell, Boston (15), 520 Commonwealth Avenue. (Alternate Howard F Root, Boston [15], 81 Bay State Road.)

WORCESTER Bancroft C Wheeler, Worcester, 27 Elm Street
(Alternate Franklyn P Bousquet, Worcester, 390 Main
Street [interim appointment])

Term Expires 1949

BARNSTABLE Paul M Butterfield, Harwich (Alternate
Paul P Henson, Hyannis, 149 Main Street)

BRISTOL NORTH Joseph L Murphy, Taunton, 23 Cedar
Street. (Alternate Curtus B Kingsbury, Taunton, 63
Prospect Street)

BRISTOL SOUTH Richard B Butler, Fall River, 278 North
Main Street (Alternate Curtus C Tripp, New Bedford,
416 County Street)

ESSEX NORTH Rolf C Norris, Methuen, 247 Broadway
(Alternate George J Connor, Haverhill, 81 Merrimack
Street)

MIDDLESEX EAST Kenneth L MacLachan, Melrose, 1 Belle-
vue Avenue (Alternate Justin L Anderson, Reading,
53 Woburn Street)

PLYMOUTH George A Moore, Brockton, 167 Newbury Street
(Alternate Alfred L Duncombe, Brockton, 38 Winthrop
Street.)

Committee on Public Relations — Established 1931 (one
councilor elected yearly by each district medical society,
the president and president-elect of the Society are
chairman and vice-chairman, respectively, and the vice-
president and secretary of the Society are members
ex-officio)

BARNSTABLE Paul P Henson, Hyannis, 149 Main Street

BERKSHIRE Patrick J Sullivan, Dalton, 471 Main Street

BRISTOL NORTH Milton E. Johnson, Attleboro, 33 Bank
Street.

BRISTOL SOUTH Harold E Perry, New Bedford, 159 Cottage
Street.

ESSEX NORTH Harold R Kurth, Lawrence, 57 Jackson
Street.

ESSEX SOUTH Loring Grimes, Swampscott, 84 Humphrey
Street

FRANKLIN Frank A Millett, Greenfield, 40 High Street

HAMPDEN Patrick E Gear, Holyoke, 188 Chestnut Street

HAMPSHIRE Joseph R Hobbs, Williamshurg, Main Street

MIDDLESEX EAST Milton J Quinn, Winchester, 44 Church
Street.

MIDDLESEX NORTH Daniel J Ellison, Lowell, 8 Merrimack
Street

MIDDLESEX SOUTH Gordon M. Morrison, Wahan Office,
Boston (15), 520 Commonwealth Avenue

NORFOLK Dean S Luce, Canton, 553 Washington Street

NORFOLK SOUTH Henry A. Robinson, Hingham, 205 North
Street.

PLYMOUTH Charles D McCann, Brockton, 12 Cottage Street.
SUFFOLK Albert A Hornor, Boston (15), 319 Longwood
Avenue.

WORCESTER Nicholas S Scarcello, Worcester, 1 Sheldon
Street.

WORCESTER NORTH James V McHugh, Leominster, 55 West
Street.

Subcommittees of the Committee on Public Relations

LABOR AND INDUSTRY — Established 1945

Daniel B Reardon (Norfolk South), *chairman*, George
J Connor, Essex North, Daniel J Ellison, Middle-
sex North, John Fallon, Worcester, and Michael A.
Tighe, Middlesex North

**COMMITTEE TO MEET WITH THE MEDICAL ADVISORY COM-
MITTEE OF THE INDUSTRIAL ACCIDENT BOARD** —
Established 1942

Daniel J Ellison (Middlesex North), *chairman*, Gordon
M Morrison, Middlesex South, and David D
Scannell, Norfolk

POSTPAYMENT MEDICAL CARE — Established 1942

Daniel J Ellison (Middlesex North), *chairman*, Michael
F Barrett, Plymouth, James H Brewster, Bristol
North, James T Brosnan, Worcester, Lucien R
Chaput, Essex North, Charles F Fasco, Berkshire,
Patrick E Gear, Hampden, Loring Grimes, Essex
South, Francis T Janitzen, Suffolk, Egon E Katt-
winkel, Middlesex South, Howard M Kemp, Frank-
lin, William B LeBrecht, Worcester North, Wilfred

L McKenzie, Middlesex East, Harold E Perry,
Bristol South, Daniel B Reardon, Norfolk South,
Harold F Rowley, Barnstable, Elmer E Thomas,
Hampshire (interim appointment) and Norman A
Welch, Norfolk

TAX-SUPPORTED MEDICAL CARE — Established 1940

Thomas Hunter (Worcester), *chairman* (interim appoint-
ment), Frederick S Hopkins, Hampden, Albert A
Hornor, Suffolk, William J Pelleter, Franklin, and
Frank W Snow, Essex North

Committee on Legislation — Established 1942 (one coun-
cilor elected yearly by each district medical society)

BARNSTABLE To be appointed

BERKSHIRE John Hughes, Pittsfield, 74 North Street

BRISTOL NORTH Curtus B Kingsbury, Taunton, 63 Prospect
Street

BRISTOL SOUTH Curtus C Tripp, New Bedford, 416 County
Street

ESSEX NORTH Nicandro F DeCesare, Methuen Office,
Lawrence, 57 Jackson Street

ESSEX SOUTH To be appointed

FRANKLIN Arthur W Hayes, Greenfield, 78 Federal Street

HAMPDEN Arthur H Riordan, Indian Orchard, 147 Oak
Street

HAMPSHIRE Lawrence N Durgin, Amherst, 66 Amity Street.

MIDDLESEX EAST John M Wilcox, Woburn, 6 Bennett
Street

MIDDLESEX NORTH Archibald R Gardner, Lowell, 16
Shattuck Street

MIDDLESEX SOUTH Kenneth J Tillotson, Belmont. Office,
Waverly, McLean Hospital

NORFOLK To be appointed

NORFOLK SOUTH David L Belding, Hingham Office, Boston
(18), 80 East Concord Street

PLYMOUTH Alfred L Duncombe, Brockton, 38 Winthrop
Street

SUFFOLK William E Browne, Boston (15), 587 Beacon Street

OFFICERS OF THE DISTRICT MEDICAL SOCIETIES FOR 1946-1947

BARNSTABLE — *President*, Harold F Rowley, Harwich Port, *vice-president*, Arthur J D'Elia, Harwich Port, *secretary*, Oscar S Simpson, Centerville, *treasurer*, Frank Travett, Barnstable, *librarian*, Sheldon L Hunt, Yarmouth Port, *executive counselor*, Paul M Butterfield, Harwich, *public relations counselor*, Paul P Henson, Hyannis

BERKSHIRE — *President*, N Newall Copeland, Pittsfield, *vice-president*, Modestino Criscitello, Pittsfield, *secretary*, Daniel N Beers, Pittsfield, *treasurer*, Theodore W Jones, Pittsfield, *executive counselor*, Isaac S F Dodd, Pittsfield, *legislative counselor*, John Hughes, Pittsfield, *public relations counselor*, Patrick J Sullivan, Dalton

BRISTOL NORTH — *President*, William M Stobbs, Attleboro, *vice-president*, Joseph V Chatigny, Taunton, *secretary*, William J Morse, Attleboro, *treasurer*, Charles E Hoye, Taunton, *executive counselor*, Joseph L Murphy, Taunton, *legislative counselor*, Curtis B Kingsbury, Taunton, *public-relations counselor*, Milton E Johnson, Attleboro

BRISTOL SOUTH — *President*, S Perry Wilde, New Bedford, *vice-president*, George W Blood, Fall River, *secretary and treasurer*, James E Fell, Fall River, *executive counselor*, Richard B Butler, Fall River, *legislative counselor*, Curtis C Tripp, New Bedford, *public-relations counselor*, Harold E Perry, New Bedford

ESSEX NORTH — *President*, Guy L Richardson, Haverhill, *vice-president*, Lincoln C Peirce, Newburyport, *secretary*, Harold R Kurth, Methuen, *treasurer*, J LeRoy Wood, Methuen, *executive counselor*, Rolf C Norris, Methuen, *legislative counselor*, Nicandro F DeCesare, Methuen, *public relations counselor*, Harold R Kurth, Methuen

ESSEX SOUTH — *President*, Charles A Worthen, Lynn, *vice-president*, Hubert A Boyle, Middleton, *secretary*, Henry D Stebbins, Marblehead, *treasurer*, Andrew Nichols, Jr., Danvers, *executive counselor*, Walter G Phippen, Salem, *public-relations counselor*, Loring Grimes, Swampscott.

FRANKLIN — *President*, John B Temple, Shelburne Falls, *vice-president*, Lawrence R Dame, Greenfield, *secretary and treasurer*, Harry L Craft, Ashfield, *executive counselor*, John E Moran, Greenfield, *legislative counselor*, Arthur W Hayes, Greenfield, *public-relations counselor*, Frank A Millett, Greenfield

HAMPSHIRE — *President*, Adolph Franz, Jr., Holyoke, *vice-president*, Arthur F G Edgelow, Springfield, *secretary and treasurer*, George C Steele, West Springfield, *executive counselor*, William A R Chapin, Springfield, *legislative counselor*, Arthur H Riordan, Indian Orchard, *public-relations counselor*, Patrick E Gear, Holyoke

5	Halpin, William Joseph, Medford	Tufts
6	*Hamburger, Herbert, Worcester	University of Pisa
6	Hamlin, Hannibal, Weston	Yale
6	*Hannon, Harland N., North Grafton	Kansas City University of Physicians and Surgeons
5	Hardy, Irad Benjamin, Jr., Waltham	Harvard
5	*Hauck, Charles Wilfred, Brookline	Middlesex
6	Heath, Wilmer Porter, Needham	Boston University
6	Heels, William Garland, North Adams	Harvard
46	Hogan, Edward Norbert, Dorchester	Georgetown University
45	Hogan, Gerald Francis, Amherst	Tufts
46	Hunt, Richard Joseph, Stoneham	Tufts
46	*Hyfer, Harry Jack, Winthrop	Middlesex
46	Isenstein, Charles, Brookline	Tufts
45	*Jacobs, Ezra Astor, Brookline	College of Physicians and Surgeons, Boston
46	*Jellinek, Kurt, Middleboro	University of Vienna
46	Joel, Samuel W., Belmont	Tufts
46	Johnson, Elwood Gordon, Waltham	Tufts
46	Johnson, Goodwin Adolph, Brookline	Tufts
46	Kane, Francis Clement, Salem	Middlesex
46	*Karp, Isadore Albert, Chelsea	Middlesex
46	*Karp, Lewis S., Worcester	Boston University
46	Kaufman, Sumner, Chelsea	Rush Medical College
46	Kaufmann, Gustav Grosvenor, Andover	Tufts
46	Keenan, George Francis, West Roxbury	Tufts
46	Kibbe, Milton Homer, West Springfield	University of Pennsylvania
46	Kirsh, David, Boston	Tufts
46	Klein, Leonard Milton, Roxbury	Tufts
46	Knox, Barron D., Springfield	Tufts
445	Koenig, Emil John, Jr., Holden	University of Bologna
445	*Kraus, Paul Stefan, North Grafton	University of Munich
446	*Kretzmer, Eugene, Worcester	Boston University
445	Lamphier, Timothy Andre, Wellesley Hills	Harvard
446	Landsteiner, Ernest Karl, Newton Centre	Tufts
445	Lapidus, Bernard, Dorchester	Tufts
446	Leary, Howard Leo, Jamaica Plain	Yale
445	Leonard, John Charles, Melrose	Harvard
446	Levenson, Stanley Mortimer, Boston	Harvard
446	Levine, Harold David, Brookline	Middlesex
446	*Levine, Louis, New Bedford	Tufts
446	Levine, Saul Charles, Malden	University of Michigan
446	Lewis, Donald King, Winchester	Harvard
445	Linenthal, Arthur Joseph, Brookline	University of Naples
446	*Litton, Nina, Brookline	University of Virginia
445	Livingston, Stanton Knowlton, West Roxbury	Middlesex
446	*London, Clarence, Lynn	University of Pennsylvania
445	Mahaney, William F., Norwood	Middlesex
446	*Mandrachia, Alfonso Charles, Everett	Tufts
446	Martinson, Melvin Stanley, Acton	Harvard
446	Matson, Donald Darrow, Boston	Georgetown University

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

Weekly Clinicopathological Exercises

FOUNDED BY RICHARD C CABOT

TRACY B MALLORY, M D, *Editor*

BENJAMIN CASTLEMAN, M D, *Associate Editor*

EDITH E PARRIS, *Assistant Editor*

CASE 32381

PRESENTATION OF CASE

A sixty-four-year-old widow, a railroad clerk, entered the hospital because of unexplained fever.

The patient had apparently been quite well until six weeks before entry, when she developed a painful, patchy erythematous, nonvesicular eruption on the left shoulder posteriorly that persisted for ten days without other symptoms and then disappeared. Following this episode she noted sharp pains and occasional ringing in the left ear. She was treated with a sulfonamide by a physician, and the symptoms cleared without residua. The patient then resumed her work. Three weeks before entry she began to have localized pain and exquisite tenderness in the nares. The area of painful inflammation progressed rapidly, and in two days the malar and nasal aspects of the face were markedly swollen, painful and red. She also developed fever and called her physician, who treated her with a mixture of oral penicillin and Amphogel for four days. Nevertheless, the lesions progressed to involve the eyes, which became red and "bloodshot" and began to burn. The temperature continued, ranging from 100 to 101°F, and was accompanied by a slight headache and anorexia. Two weeks before entry the face involvement had subsided, but the sides and back of the neck, the temporomandibular joints, the occipital region of the scalp and the ears were affected. These areas were hot and red, and in the suboccipital region a small egg-sized mass developed subcutaneously. The condition grew worse until the patient was partially deafened and was awakened nightly by sharp severe pains, especially in the back of the neck, and occasional twinges in both ears. She had lost about 10 pounds during the six weeks before admission.

As an adolescent the patient had had an attack of erysipelas, during which she became quite sick and developed corneal ulcers. Following this illness aching pains in the shoulders had developed. Ten years before entry the patient had spent nine months at a tuberculosis sanatorium because of pleuritic pain in the left chest and weight loss. The tongue had been sore for about two years. Occasional

episodes of urinary frequency, burning and gross hematuria had also occurred during the preceding few years, particularly during the previous six months.

Physical examination revealed a thin woman in no obvious distress, although she complained of tenderness in both temporal regions and along the sternomastoid muscles. The eyes showed old peripheral corneal scars. The ear canals and margins of the drums were somewhat inflamed, particularly on the left. The Weber test was lateralized to the left, and bone conduction was better than air conduction on both sides. The mouth was fissured at the angles, and the tongue was beefy red and sore, with coarse papillae. There was general swelling and slight lymphadenopathy in the region of the left sternomastoid muscle. The lungs were clear, except for a few moist rales at the left base. The heart did not appear enlarged. A blowing systolic murmur was heard at the apex but was not transmitted into the axilla. There was also a soft, blowing systolic murmur over the aortic area. The sounds were regular and of good quality. The abdomen was normal except for slight epigastric tenderness.

The temperature was 101°F, the pulse 100, and the respirations 24. The blood pressure was 160 systolic, 90 diastolic.

Examination of the blood revealed a hemoglobin of 12.5 gm and a white-cell count of 12,600, with 86 per cent neutrophils, 3 per cent lymphocytes, 5 per cent monocytes, 4 per cent eosinophils and 1 per cent basophils. The sedimentation rate was 6 mm in 1 hour. Blood Hinton and Vidal reactions and a brucellergin test were negative, as were five blood cultures. The urine had a specific gravity of 1.014 and showed a ++ test for albumin, the sediment contained 5 red cells and 25 white cells per high-power field.

An x-ray film of the chest showed only irregular areas of calcification about the right hilus and in the right apical region. Examination of the sinuses, a gastrointestinal series and intravenous pyelogram were all negative. A Graham test showed a poorly functioning gall bladder.

The patient was placed on a high-vitamin, high-calorie diet but failed to improve. On the fifth hospital day an episode of urinary frequency and burning, lasting for several hours, occurred. A urine culture was negative, and no acid-fast organisms were seen in a smear. Sulfathiazole was given. On the seventh hospital day a scratchy sound in late midsystole was picked up in the third and the fourth interspace at the left sternal border. Pressure on the bell of the stethoscope brought this sound closer to the ear. The patient was then taken off sulfathiazole and started on salicylates. For the next several days she appeared subjectively improved, although she complained that the deafness was becoming worse. On the tenth hospital day an electrocardiogram was reported to be within normal limits. An

ascertain from the clinical record. At the time of admission the patient had fever, and there was evidence of serous-membrane involvement. Subsequently she developed a migratory arthritis involving a number of articulations and experienced recurring attacks of abdominal pain. This train of events is readily accounted for on the basis of a disease characterized by widespread vascular lesions, such as lupus erythematosus disseminatus, dermatomyositis or periarteritis nodosa. The choice of the proper diagnosis is always difficult, because experience has shown that there may be much overlapping of both clinical and pathological findings in cases of this type. During the last ten years we have seen a number of patients with clinical findings not unlike those observed in the case under discussion. In each case the clinical diagnosis of lupus erythematosus disseminatus was agreed to by Dr Mallory on the basis of the pathological examination. The exact cause of the cardiac enlargement, which was observed during the last days of the patient's life, is difficult to establish. It could have been a pericardial effusion, diffuse cardiac enlargement or right-sided cardiac enlargement secondary to periarteritis nodosa of the pulmonary vascular system. Such enlargement has been observed in lupus erythematosus disseminatus. I cannot prove its presence in this case, but it is a good possibility.

The laboratory findings are of little help. A white-cell count of 13,000 to 30,000 has been noted in lupus erythematosus disseminatus, particularly in the terminal stages of the disease. Leukopenia is thought by some to be a characteristic finding. In our experience, however, it occurs in only about 50 per cent of the cases of disseminated lupus. I have always been struck by the fact that many cases of periarteritis nodosa have a much higher white-cell count than one would anticipate on the basis of the fever.

In summary, I shall say that this was a case of disseminated lupus erythematosus. I shall not be surprised if Dr Mallory reports the finding of vascular lesions that were indistinguishable from those of periarteritis nodosa.

DR RICHARDSON: I saw this patient in consultation once after she had been in the hospital two weeks and before a great many terminal events had occurred. I also do not know what the diagnosis is. At the time I saw her I thought she had a peculiar lack of immunity to a streptococcal infection that could have been erysipelas. After hearing the story my opinion is that she had this infection and that she developed nephritis and pericarditis as a terminal event.

DR BAUER: Let us not lose sight of the fact that genitourinary symptoms and gross hematuria had been present eight to twenty months before the erysipelas or erysipeloid lesions appeared.

DR RICHARDSON: Nephritis may have been the first sign.

DR BAUER: As a general rule one is on much safer

ground in assuming that a patient of this age has several diseases. There can be no doubt that this patient had renal disease. Whether it was an independent pathologic process or a manifestation of a systemic disease, Dr Mallory will soon tell us. I have already committed myself, and I shall stick to my diagnosis of lupus erythematosus disseminatus.

DR RICHARDSON: I think that you are going to be wrong.

DR BAUER: It will not be the first time. It is important to realize that the patient's sex and age do not rule out the presence of widespread vascular disease of the type discussed.

DR LEWIS K DAHL: Do you think that this patient's age is a little more in favor of periarteritis nodosa than disseminated lupus?

DR BAUER: No, I do not. On reviewing the cases recorded in the literature one finds that the disease occurs in any age group. Therefore, when one is concerned with a single case, the age of the patient is of no diagnostic help. The same fact is true of sex in both disseminated lupus and periarteritis nodosa. Eighteen per cent of cases of the former occur in men.

CLINICAL DIAGNOSIS

Periarteritis nodosa?

Lupus erythematosus?

DR. BAUER'S DIAGNOSIS

Lupus erythematosus disseminatus, with widespread vascular lesions of type seen in periarteritis nodosa.

ANATOMICAL DIAGNOSES

Periarteritis nodosa.

Multiple infarcts of liver and kidneys.

Pericarditis, fibrinous, mild.

Mural thrombus of right auricle.

PATHOLOGICAL DISCUSSION

DR MALLORY: The autopsy in this case showed a pericarditis less marked anatomically than might have been expected from the clinical evidence. The heart was slightly enlarged, weighing 390 gm. The endocardium and valves were normal, but there was a thrombus in the right auricular appendage and a moderate degree of coronary sclerosis, without occlusion in any vessel. The pleural cavities contained 500 cc of fluid on each side, but showed no evidence of inflammation. The liver was quite peculiar. Both the external and the cut surfaces were irregularly mottled with focal dark areas 5 to 10 mm in diameter. In each of these areas the centers of the lobules were large, red and depressed, as in chronic passive congestion. This is the characteristic gross picture of infarction in the liver, which is rarely complete because of the double blood supply and because only those cells in the center of the lobules are killed. The kidneys likewise showed multiple infarcts—in fact, they were so numerous that the picture was suggestive of diffuse cortical necrosis,

erysipeloid lesion about the right ear was again prominent, and penicillin therapy was begun. On the twenty-second hospital day she developed an urticarial rash, which disappeared after penicillin was stopped. Five days later bilateral shoulder pain, with swelling and tenderness on the left, occurred and lasted for three days, being followed successively by a hot, swollen, tender right wrist, a painful, swollen left infrapatellar tendon, a tender left wrist, pain over the scapula region of the back, increased epigastric pain and tenderness with spasm and an attack of numbness in the fingers and thumb of the right hand. The patient continued to suffer from severe malaise, listlessness and anorexia. The pericardial friction rub remained constant. The temperature usually rose to 101° or 102°F in the evening. The white-cell count ranged from 13,000 to 30,000. The sedimentation rate reached 50 mm in 1 hour. Repeated urine examinations showed + or ++ tests for albumin and 5 to 100 red cells per high-power field. Tenderness in the left costovertebral angle was also noted. The patient grew progressively worse. Several transfusions of whole blood brought about only temporary improvement.

On the fifty-second hospital day a pronounced gallop rhythm was heard over the entire precordium. The neck veins became distended. Cyanosis and puffiness of the face were noticeable. Crackling rales were heard at both lung bases. The liver edge was percussed four fingerbreadths below the costal margin. There was slight pitting edema over the sacrum. Nevertheless, the patient was not dyspneic or orthopneic. The pulse was 110, and the blood pressure 175 systolic, 105 diastolic. Repeated blood chemical studies revealed a nonprotein nitrogen of 107 mg and a total protein of 5.9 gm per 100 cc. On the fifty-fourth hospital day, the patient complained of memory loss and pain in the abdomen. The heart was markedly enlarged to percussion, with the point of maximum impulse in the axilla, and a pronounced to-and-fro friction rub was heard over the entire precordium. The urinary output dropped to 60 cc. The patient became stuporous, developed muscular twitching and died on the fifty-eighth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. WALTER BAUER: Did the pain arise in the temporomandibular joints or the adjacent muscles?

DR. TRACY B. MALLORY: I do not know.

DR. BAUER: Was it erysipelas or an erysipeloid lesion that developed?

DR. MALLORY: The word "erysipeloid" was used.

DR. BAUER: Was the egg-sized mass a lymph node?

DR. WYMAN RICHARDSON: I saw this patient once but not at that time. I assume that it was a lymph node.

DR. BAUER: I wonder if anyone who saw the patient would be willing to say whether or not the pain followed the course of the arteries.

DR. RICHARDSON: I did not observe it.

DR. BAUER: If I ask any more questions you will know the diagnostic possibilities that I am entertaining.

I interpret the deafness as being of the middle ear type, but more marked on one side. The Weber test as reported does not rule out bilateral nerve deafness. Were urinary cultures and guinea pig inoculations for acid-fast organisms done?

DR. MALLORY: There is no record of such tests.

DR. BAUER: I assume that the beneficial effect of salicylates was short lived.

DR. MALLORY: That is correct.

DR. BAUER: Does anyone know the duration of the circulatory changes described? Were they neurogenic in origin?

DR. RICHARDSON: Again, I must say that I saw the patient before that episode and that I do not know.

DR. BAUER: Will Dr. Lingley show the roentgenograms of the chest and the intravenous pyelograms? I doubt if the gastrointestinal series will be of interest. I assume that the pulmonary findings described were the result of an old acid-fast infection.

DR. JAMES R. LINGLEY: The film of the chest as described shows areas consistent with old tuberculosis of the apex and hilus. The heart is normal. There is evidence of old pleurisy at the left base. On the pyelogram there is excretion from both kidneys, and no abnormalities are demonstrable. On this film the Graham test shows a rather faint shadow.

DR. BAUER: On the basis of this information one wonders if this patient had one or several diseases and when the illness or illnesses began. According to the record, she spent nine months in a tuberculosis sanatorium nine years before admission and was later observed to have pulmonary findings consistent with healed tuberculosis. The genitourinary symptoms, which had been present for at least two years, could have been caused by an acid-fast infection, as the physician in charge suspected. The cutaneous lesions could have been those of erysipelas, and the subsequent serous membrane involvement a manifestation of an ensuing rheumatic fever. Such a sequence of events would account for all the recorded findings. I prefer to reason, however, that the patient suffered from a constitutional disease due to widespread vascular lesions that was first demonstrated by renal involvement. Perhaps I reason this way because of my interest in a special group of diseases. The second manifestation of this patient's illness — the appearance of cutaneous lesions, first over the posterior aspect of one shoulder and later involving the face and neck — is in accord with this concept. Such cutaneous lesions are seen in both disseminated lupus erythematosus and dermatomyositis, but more frequently in the former. Whether the muscles of the face and neck were involved is difficult to

ascertain from the clinical record. At the time of admission the patient had fever, and there was evidence of serous-membrane involvement. Subsequently she developed a migratory arthritis involving a number of articulations and experienced recurring attacks of abdominal pain. This train of events is readily accounted for on the basis of a disease characterized by widespread vascular lesions, such as lupus erythematosus disseminatus, dermatomyositis or periarteritis nodosa. The choice of the proper diagnosis is always difficult, because experience has shown that there may be much overlapping of both clinical and pathological findings in cases of this type. During the last ten years we have seen a number of patients with clinical findings not unlike those observed in the case under discussion. In each case the clinical diagnosis of lupus erythematosus disseminatus was agreed to by Dr. Mallory on the basis of the pathological examination. The exact cause of the cardiac enlargement, which was observed during the last days of the patient's life, is difficult to establish. It could have been a pericardial effusion, diffuse cardiac enlargement or right-sided cardiac enlargement secondary to periarteritis nodosa of the pulmonary vascular system. Such enlargement has been observed in lupus erythematosus disseminatus. I cannot prove its presence in this case, but it is a good possibility.

The laboratory findings are of little help. A white-cell count of 13,000 to 30,000 has been noted in lupus erythematosus disseminatus, particularly in the terminal stages of the disease. CLINICAL DIAGNOSIS

Periarteritis nodosa?

Lupus erythematosus?

DR. BAUER'S DIAGNOSIS

Lupus erythematosus disseminatus, with widespread vascular lesions of type seen in periarteritis nodosa.

ANATOMICAL DIAGNOSES

Periarteritis nodosa

Multiple infarcts of liver and kidneys.

Pericarditis, fibrinous, mild

Mural thrombus of right auricle

PATHOLOGICAL DISCUSSION

DR. MALLORY: The autopsy in this case showed a pericarditis less marked anatomically than might have been expected from the clinical evidence. The heart was slightly enlarged, weighing 390 gm. The endocardium and valves were normal, but there was a thrombus in the right auricular appendage and a moderate degree of coronary sclerosis, without occlusion in any vessel. The pleural cavities contained 500 cc. of fluid on each side, but showed no evidence of inflammation. The liver was quite peculiar. Both the external and the cut surfaces were irregularly mottled with focal dark areas 5 to 10 mm. in diameter. In each of these areas the centers of the lobules were large, red and depressed, as in chronic passive congestion. This is the characteristic gross picture of infarction in the liver, which is rarely complete because of the double blood supply and because only those cells in the center of the lobules are killed. The kidneys likewise showed multiple infarcts—in fact, they were so numerous that the picture was suggestive of diffuse cortical necrosis,

although the process was a little too spotty and there were some uninvolved areas. The spleen was grossly normal. On the basis of the multiple areas of infarction in the liver and the kidney it seemed to me that a diagnosis of periarteritis nodosa was inevitable.

When the microscopic sections came through we found vascular lesions in many areas. There was rather marked involvement of the bronchial arteries, although the patient had never had any pulmonary symptoms. Many vessels in the liver and the spleen and the kidney showed lesions of various ages and character. In some the process seemed to be primarily endarteritis, in others occlusive thrombosis, and in a few areas typical periarteritis nodosa, with necrosis of the media, aneurysm formation and so forth. One section from the deltoid muscle showed a typical periarteritic lesion. There was nothing in the case that particularly indicated a diagnosis of lupus, although there was periarterial fibrosis in the spleen, which is consistent with it. The kidney lesions were not suggestive. In several sections from the brain we were unable to find arterial lesions.

DR BAUER: Did the patient ever exhibit jaundice?

DR MALLORY: It was never noticed.

DR RICHARDSON: What do you think of the relation of sulfonamide therapy to this picture?

DR BAUER: I do not know. So far as one can judge from the record the first erythematous lesions appeared prior to sulfonamide therapy. On the basis of past experience and recent experimental studies I should not administer sulfonamides to a patient suspected of having widespread vascular disease of the type mentioned. Whether sulfonamides were a cause in this case, I cannot say.

DR RICHARDSON: You do not believe that they were a cause?

DR BAUER: No, for the reasons previously mentioned.

This case, like others we have seen, illustrates the difficulties the clinician may have in making an accurate anatomical diagnosis. We have seen patients in this hospital who presented the classic textbook picture of disseminated lupus, and yet Dr Mallory made a diagnosis of periarteritis nodosa on the basis of the microscopic findings. The onset of the disease in this patient resembled both disseminated lupus and dermatomyositis. The subsequent course was more like that of disseminated lupus or periarteritis nodosa. Was this another overlapping case of the type mentioned? I know of no similar case of periarteritis nodosa on record, although Keil* reported the appearance of a red, painful, cutaneous lesion as the first manifestation of the disease in 1 case. Can it be that these diseases, which simulate one another so closely, represent different manifestations of a common pathogenesis? Have you ever seen a case like this, Dr Ropes?

DR MARIAN ROPES: No.

DR MALLORY: There is no evidence to add from

the anatomical point of view. There was a wide variety of vascular lesions, some acute, some certainly of months' duration, and some possibly going back two years, although I cannot say that definitely.

CASE 32382

PRESENTATION OF CASE

A seventy-one-year-old retired shoe laster entered the hospital because of bloody urine.

Seven years before entry the patient had had an attack of acute urinary retention, and a suprapubic prostatectomy had been performed at another hospital, following which intermittent painless hematuria and the occasional passage of small blood clots had begun. A year later, cystoscopy was performed at the same hospital and a section of tissue removed from a "growth in the bladder." This procedure effected marked improvement, although the urine continued to be occasionally bloody. Three months before entry almost daily hematuria suddenly began, with frequent passage of clots. Two months later cystoscopy in the Out Patient Department disclosed no source of the bleeding. An intravenous pyelogram showed an enlarged left kidney that failed to excrete the dye during the twenty-minute observation period, the right kidney appeared normal. The bones of the pelvis showed a coarse trabeculation and thickening of the cortex. Shortly thereafter the patient had an episode of urinary retention and was kept on constant drainage at the other hospital for four days. He also developed chills, nausea, vomiting and pain in the left flank and lost 10 pounds in weight. These symptoms persisted. Three days before entry the patient was again cystoscoped in the Out Patient Department, and bright-red blood was seen to come from the left ureter even when the catheter was inserted up to 25 cm. Considerable reddening and some small nubbins-like projections were found about the left ureteral orifice. A retrograde pyelogram did not give satisfactory filling of the left kidney pelvis. The kidney calyces appeared enlarged, and there was a suggestion of a rather large, smooth, filling defect against the neck of the upper calyx and the pelvis. The kidney outline was not clearly seen on any of the films.

Physical examination on admission revealed an increase in the anteroposterior diameter of the chest, as well as poor expansion. The heart was normal. A large, warm, tender mass, with a somewhat softer center than normal, was present at the left costovertebral angle and extended into the left flank. The entire left side of the abdomen was moderately tense and tender. The liver appeared to be somewhat enlarged.

The temperature, pulse and respirations were normal. The blood pressure was 135 systolic 80 diastolic.

Examination of the blood revealed a hemoglobin of 75 per cent and a white-cell count of 10,600.

*Keil, H. Conception of lupus erythematosus and its morphologic variants, with particular reference to 'systemic' lupus erythematosus. *Arch. Dermat. & Syph.* 36: 729-757, 1937.

The urine, which was amber colored and acid, had a specific gravity of 1.012 and gave a +++ test for albumin. The sediment contained 250 red cells and 250 white cells, with many clumps, per high-power field. Culture revealed abundant colon bacilli. X-ray examination of the chest was negative. A biopsy of the bladder was reported as showing malakoplakia.

During the first week in the hospital the mass in the left costovertebral angle became larger, warmer and definitely fluctuant in several places, although the patient had no fever and only a slight leukocytosis. Aspiration produced 4 cc of brownish pus that showed a slight growth of colon bacilli and aerobic gram-positive bacilli.

On the tenth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. FIORINDO A. SIMEONE This patient had had painless hematuria for seven years, but the presenting symptoms when he was admitted to the hospital were chills, nausea, vomiting, pain in the left flank and weight loss. The physical examination showed the usual signs of inflammation in the left flank. In addition, brownish pus was aspirated from the mass in the flank. A diagnosis of perinephric abscess can therefore be made without much question. Incidentally, the physical examination and x-ray studies suggest that there was no gross lesion other than that in the genitourinary tract. The slight enlargement of the liver was probably of no significance. The heart and lungs were normal on x-ray and physical examination. The peripheral edema could have been the result of malnutrition during the month or more prior to admission, and it could have been associated with hypoproteinemia caused by the loss of blood and protein in the urine during the long period of illness.

Patients with perinephric abscesses can be classified in two main groups — simple and complicated. The distinction is important because both etiology and prognosis are different in the two groups. Simple perinephric abscess is the type secondary to metastasis of organisms from foci of infections elsewhere, such as carbuncles, furuncles and severe tonsillitis. The usual organism is *Staphylococcus aureus* or the streptococcus. The complicated type, which has a relatively poor prognosis, is encountered in patients who, as a rule, have had long-standing infection in the kidney that has spread through the renal parenchyma and into the perinephric space. Later, such infection may actually perforate Gerota's capsule and point in the costovertebral angle. The symptoms and signs recorded in the history of this case are consistent with a diagnosis of complicated perinephric abscess. The patient had gross infection in the left kidney, as manifested by the presence of red cells and large numbers of white cells in the urine and by the culture of colon bacilli — presumably the same organism cultured from the

pus aspirated from the flank. No function could be demonstrated in the left kidney by excretory roentgenography.

What was the cause of the pyelonephritis in this case? Seven years before admission a suprapubic prostatectomy had been performed after acute urinary retention that was presumably caused by benign hypertrophy of the prostate. It is possible, on the other hand, that the retention developed because of the presence of blood clot or tissue fragments in the bladder. These could have arisen from a malignant tumor of the kidney or ureter, but there is no information to help settle the question and it should be assumed that the prostatectomy was done for benign hypertrophy. The state of the kidneys at that time is not mentioned. It is customary to investigate the kidneys before prostatectomy, particularly after an episode of acute retention, but the record does not state whether such examination was made, consequently, one is not justified in assuming that the left kidney and ureter were normal.

DR. BENJAMIN CASTLEMAN No pyelograms were done at the other hospital.

DR. SIMEONE It is natural to ask if the present illness could have been a late sequela or complication of suprapubic prostatectomy. The pyelonephritis and subsequent perinephric abscess could have resulted from chronic obstruction of the urinary tract. Massive hemorrhage is possible but rather infrequent. The process is bilateral and involves the ureters. The x-ray studies done in this hospital do not suggest such involvement.

The most significant fact is the painless hematuria for seven years in a seventy-one-year-old man. It is reasonable to assume that whatever caused the hematuria was responsible for the pyelonephritis and for the extension of the infection into the perinephric tissues. The record states that blood was seen to come from the left ureter. That excludes from the causes of hematuria the numerous associated systemic conditions and limits the possibilities considerably. In addition blood was flowing not only from the ureter but also from the renal pelvis, because it was obtained from the ureteral catheter that was passed 25 cm — well into the renal pelvis. The additional information is that cystoscopy revealed no cause for the bleeding in the bladder. If a papilloma of the bladder had been present at cystoscopy and operation six years previously, and if a small section of the lesion had been removed, there should have been residual evidence of the lesion at examination in this hospital. There was reddening around the ureter, with nubblike projections about the ureteral orifice, a biopsy of which showed malakoplakia. Perhaps Dr. Castleman will tell us more about the histology of this lesion. Attempts have been made to relate malakoplakia to tuberculosis or mycotic infection in the kidney, but the evidence is not generally accepted and about all that one can say about malakoplakia

is that the condition is associated with chronic and prolonged infections in the kidney, ureter and bladder.^{1, 2}

This brings the discussion to the point that is usually reached in trying to determine the cause of hematuria, and help from the roentgenologist is needed. The record states that there was a filling defect in the renal pelvis and neck of the calyx. It might be interesting to have Dr. Schulz show the films.

DR. MILFORD D. SCHULZ: These films, which are representative of the two examinations made, show a definite pressure defect on the calyces, which are rather ragged in outline and larger than usual. The kidney outline is not visible. There is no calcification in the kidneys, merely dye extravasated into the destroyed kidney parenchyma. The ureter is not visible.

DR. SIMEONE: Is there any irregularity in the calyx itself at that point?

DR. SCHULZ: I do not know. Certainly it looks as if something is compressing it. A lateral film would be helpful.

DR. SIMEONE: Can you be certain whether the filling defect is caused by a lesion outside or within the pelvis?

DR. SCHULZ: I think that it is probably outside the pelvis, but whether or not it is outside the kidney I am not sure. It seems as though the pelvis is being pressed on by some mass.

DR. SIMEONE: Is this calyx dilated?

DR. SCHULZ: All are wider than they should be.

DR. SIMEONE: Is there any evidence of nonopaque stone obstructing the ureteropelvic junction?

DR. SCHULZ: None that I can see. This is Paget's disease down here in the pelvis, that is the only part of which I am sure.

DR. SIMEONE: One can explain the trabeculations in the bones of the pelvis, as Dr. Schulz has said, on the basis of Paget's disease. I do not know any way of connecting the bone disease with the renal lesion. In reviewing some of the possible causes of hematuria in this case, the record of brown pus from the abscess and the slight enlargement of the liver suggested amebic abscess, but I do not know of amebic abscesses that occur in the kidney as they do in the liver. The roentgenograms and the characteristics of the aspirated pus are not consistent with actinomycosis or tuberculosis, which could account for both the hematuria and the chronic infection resulting in the malakoplakia. Tuberculosis as a cause of painless hematuria is unusual in a patient of this age. Painless hematuria occurs early in tuberculosis of the kidney, and renal tuberculosis is generally found under the age of forty. I do not believe that there is evidence of stone, opaque or nonopaque.

The diagnosis of tumor and infection therefore remains. The only question remaining is what type of tumor was present. If the hematuria had been due to this tumor and had lasted for seven years,

malignant tumor, although possible, would be unusual. The roentgenogram is consistent with either a malignant tumor or a benign cyst. If the latter had been the lesion involved, it is conceivable that the aspiration of brownish fluid would have come from the cyst rather than from a perinephric abscess. All the findings, however, favor perinephric abscess. My diagnosis is tumor of the kidney, probably a cyst, with perinephric abscess and acute and chronic pyelonephritis.

DR. WYLAND F. LEADBETTER, JR.: We worried for some time about the diagnosis in this case. A fluctuant mass was present in the flank from which we aspirated pus, on the basis of which we believed that the patient had a perinephric abscess. We were unable to ascribe a definite diagnosis to the kidney lesion itself. The main criticism up to this point is that we did not have the necessary x-ray films. We should have had oblique and lateral films, which would probably have given considerable help.

CLINICAL DIAGNOSES

Perinephric abscess, possibly secondary to tumor of kidney

Pyelonephritis, acute and chronic

DR. SIMEONE'S DIAGNOSES

Perinephric abscess, secondary to tumor of the kidney, probably benign cyst

Pyelonephritis, acute and chronic

ANATOMICAL DIAGNOSES

Perinephric abscess secondary to renal-cell carcinoma

Pyelonephritis, acute and chronic

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: At operation the surgeon found an abscess on the posterior aspect of the kidney over Gerota's capsule. A large quantity of purulent material was drained from it. Further exploration of the kidney, however, showed that its posterior aspect, beyond this abscess, contained a great deal of necrotic material, which grossly suggested a tumor. For that reason the entire mass was removed after the incision was extended upward for a considerable distance. The mass, which was removed in two pieces, because it was so necrotic, proved to be an unusual renal-cell carcinoma. It was quite slowly growing, and it is not inconceivable that this neoplasm had been present for seven years. We have had a number of cases in which the tumor was present for a long time.

The patient was seen yesterday afternoon at the Tumor Clinic, and the note by the physician who saw him states that there had been no further hematuria, the patient felt fine, the urine was clear, and nothing could be felt in the flank.

MATERNAL AND CHILD WELFARE

THE altercation between Senators Taft and Murray during the recent hearings on the Wagner-Murray-Dingell Bill, although an unfortunate reflection on the dignity of the highest legislative body in the land, had the merit of dramatizing an encouraging phenomenon in the midst of discord the need for better medical, hospital and nursing care for all people in the United States is recognized by all parties. Disagreements represent conflicting opinions regarding methods and are not concerned with denying that improvement must be provided, the opponents of the bill objecting to any extension of government paternalism and interference and the supporters claiming that only through legislation can better care for all classes of

citizens be guaranteed. If the latter ideology is not to prevail, the medical profession must accept the responsibility of inaugurating the reform that is unanimously demanded.

A crucial part of any program, compulsory or voluntary, for the extension of medical care is adequate provision for the health and welfare of mothers and children. Numerous flaws in the Government's attempt to remedy the existing shortcomings in this field—the Pepper Bill—have been pointed out.¹ This is not to say that the objectives of the bill, as stated in the introduction, do not have the full approval of the medical profession. But the methods by which those objectives are to be achieved represent not only a threat to many basic ideals and principles of the profession but also, in many respects, an inefficient and unworkable approach that may well work to the disadvantage of the classes that the bill is designed to benefit.

This and similar legislation offers a challenge to the medical profession. If government interference is to be averted, the inadequacies and inequities of maternal and infant care in many areas, particularly among indigent classes, must be recognized and corrected by the concerted effort of physicians. The following factors in the care of all mothers and infants must be given special consideration: the need for obstetricians qualified by training and experience to provide adequate care in pregnancy, labor and delivery, as well as post partum, adequate nursing care and instruction to prepare the new mother for the duties of parenthood, access to special consultation services in the event of complications, hospitals with sufficient staffs and facilities to furnish continuous maternal and infant care, and the benefit of the newest and best developments in diagnosis and therapy, regardless of cost. A notable example of what can be accomplished by a voluntary approach to the problem is provided by the Chicago Lying-in Hospital.² During the past thirteen and a half years 47,945 obstetric patients were cared for at this institution, with 81 deaths, a mortality rate of 0.17 per cent, but during that period the mortality rate fell from 0.42 per cent in 1931 to zero in 1944. Undoubtedly such an outstanding achievement cannot be obtained in

all parts of the country, but it can be and is being approached. The pattern of the Blue Cross and the Blue Shield should be extended to include all sections of the country, all classes of the population and all types of medical care existing programs of prepayment hospital and medical care offer proof that the medical profession can take the lead in co-operation for the public welfare.

Democracy often works in strange and wondrous ways, the existence of inequalities being a major paradox. In many states the Negro is disenfranchised, and efforts to remedy the injustice are met with opposition and terrorization of the subject race, in other parts of the country the necessities of life and health are beyond the reach of a large segment of the population. When such inequalities are discussed in the halls of Congress and, what is more important, constructive attempts at correction are undertaken by the groups most intimately concerned, the fullest benefits of our way of life offer promise of realization. The role of physicians in these efforts is vital.

DIAGNOSIS OF MALARIA

Two papers appearing elsewhere in this issue of the *Journal* serve as useful examples to point out problems that confront civilian physicians in diagnosing and treating malaria. These are occurring with sufficient frequency to warrant emphasis on methods for their solution. Three primary situations exist. Discharged veterans or men on inactive duty who were exposed to infection in malarious areas while under suppressive treatment are likely to come down with delayed primary attacks of vivax malaria. A previous history of malarial attacks caused by *Plasmodium vivax* is the basis for subsequent relapses over a period of one to three years. Finally, malaria may develop in a patient receiving transfusions of fresh or stored whole blood from donors who are infected with benign tertian or quartan malaria. No figures are available for the actual frequency of each of these situations.

Nevertheless, acquaintance with the underlying facts obtained from the extensive experience of others is pertinent to physicians who are likely to be consulted by persons who served in endemic malarious areas.

The protean character of primary attacks of malaria is well illustrated by London and Most in their warning about differential diagnosis. Bacterial and certain viral infections must be distinguished from malaria. Abdominal symptoms simulating an acute surgical abdomen may also occur during the first few days of clinical malaria. The number, type and intensity of symptoms of primary malarial attacks unfortunately are seldom typical in the textbook sense. Thus, before a diagnosis is made on clinical evidence and treatment is begun, the blood should be thoroughly examined for malarial parasites. The immediate prescription of chemotherapy with sulfonamides or antimalarial drugs without adequate search for parasites only prolongs the time required to make a positive diagnosis and administer curative treatment.

The search for plasmodia before the intervention of chemotherapy frequently fails because of the low incidence of the organisms during the beginning of the primary clinical attack. As few as ten parasites or less per cubic millimeter are sufficient to cause the first febrile attack.¹ According to the figures of London and Most, 54 per cent of the primary attacks and 31 per cent of the relapses with *P. vivax* had less than a thousand parasites per cubic millimeter of blood or approximately one parasite for five thousand erythrocytes. Thus, to request a routine laboratory examination for malarial parasites is not enough. The diagnosis should be made by persons with experience in the improved thick-film and thin-film staining techniques and in the specific identification of the parasites. For low concentrations of parasites, the thick-film methods using the Giemsa, Wright-Giemsa or other suitable staining procedures must be employed for satisfactory results. A routine Wright's stain of the blood films does not ordinarily demonstrate the parasites. Failure to find the parasites is usually detrimental to the patient, since it misleads the clinician in prescribing treatment.

If the patient is carrying malarial parasites and

not properly treated, transmission of the disease to others by anopheline mosquitoes becomes possible. In the northern part of this country, the breeding season for vectors of malaria is limited to the midsummer months. In the midland and southern United States, however, transmission is possible for a greater part of the year. Since Young et al.² have proved that native anophelines, *Anopheles quadrimaculatus* and *A. punctipennis*, can transmit malarias of foreign origin and that patients are infectious for anopheline mosquitoes so long as they are subject to relapse, early diagnosis and effective treatment are desirable for control purposes.

That transfusions with whole blood can lead to clinical malaria has been known in this area for many years.³ In the case cited by Fischer and York transfusion of whole blood stored five to twelve days leads to malaria, and this can be expected to happen more frequently as the methods for preserving whole blood improve. The submicroscopical levels of circulating parasites in these donors with a previous malarial history and the absence of an effective serologic method to detect latent infection leave no alternative other than the rejection of blood from those who have had a past infection, however remote. The relatively long incubation period of transfusion malaria in many cases and the low grade of parasitemia are the features that may confuse the clinician. Here again, blood films should be prepared and examined by skilled technicians to arrive at the correct diagnosis.

DEATH

SULZBACH — Wolfgang Max Ferdinand Sulzbach, M.D. of Boston, died recently. He was in his thirty-eighth year. Dr. Sulzbach received his degree from Rheinische Friedrich-Wilhelms-Universität Medizinische Fakultät, Bonn, Prussia in 1933. He was a member of the staff of the McLean Hospital.

MISCELLANY

PROGRAM ON CARE OF THE HEART

Interest in the control of heart disease is currently being enhanced by the efforts of many professional and lay groups. This attention to heart ailments has long been warranted. The public is becoming more acutely aware of cardiac hygiene than ever before — a growing interest that should be cultivated and guided with judgment as well as vigor.

During the past third of a century, the improvement in mortality from heart disease was most pronounced in the younger age groups and decreased progressively with advance in age. The death rate from diseases of the heart and arteries, corrected for the aging of the population, dropped virtually 30 per cent between 1911-15 and 1940-44, according to experience among the industrial policyholders of the Metropolitan Life Insurance Company. This reduction in mortality from the principal cardiovascular-renal diseases has been particularly marked among white females — 37 per cent in the above-mentioned period. Among males, the decrease in mortality, although not so marked as that among females, was 25 per cent, still a substantial reduction. This still leaves much to be desired in the field of early diagnosis and immediate initiation of adequate cardiac regimes to reduce to a minimum incapacity and mortality from these conditions. Concentration of effort must now be placed on teaching the public what is known about prevention, early recognition and care of cardiac lesions.

To assist in the attainment of this goal, the Metropolitan Life Insurance Company is conducting a special campaign on heart disease during the fall and winter months. At that time, more than 20,000 field representatives, in co-operation with official and voluntary agencies, will reach the homes of millions of policyholders with a recently published pamphlet, "Your Heart," developed in co-operation with the American Heart Association. A lay educational film on heart disease is also being prepared. Distribution will be made to physicians of a packet in which will be included material of special interest to doctors. A scientific exhibit on heart disease, first shown at the meeting of the American Medical Association in San Francisco, is available for state and local professional meetings.

BOOK REVIEWS

Periodontal Diseases and Soft Tissue Lesions of the Oral Cavity: Diagnosis and Treatment. By Arthur H. Merritt, M.S., D.D.S., Sc.D. Third edition. 8°, cloth, 256 pp., with 53 illustrations. New York: Macmillan Company, 1945. \$3.50.

The third edition of this book has an added section, consisting of six short chapters and nine illustrations, entitled "Soft Tissue Lesions of the Oral Cavity." In the opinion of the reviewer, this section, which gives a superficial and inadequate discussion of lesions of the mucous membrane, with a few rather poor illustrations, detracts from rather than enhances the value of the book, which offers useful practical information — based on extensive clinical experience in the diagnosis and treatment of periodontal diseases — regarding the management in office practice.

Recent advances in the knowledge of periodontal diseases are not referred to, and the bibliography is incomplete and fails to satisfy the inquiring mind of the student or practitioner of dentistry.

The Psychology of Women: A psychoanalytic interpretation. Volume II. *Motherhood*. By Helene Deutsch, M.D. 8°, cloth, 498 pp. New York: Grune and Stratton, 1945. \$4.50.

Rarely does a reviewer have the pleasure of studying a book of this type. Dr. Deutsch has presented her second volume of this broad and controversial field with a clarity, construction and determined purposefulness that is often lacking in psychologic and psychoanalytic literature. The reviewer highly recommends this book to all professional members of allied psychiatric services.

The text develops the theme of most of the psychologic, really psychoanalytic, factors in maturing and older women. The chapters that seemed to have outstanding informative clarity were those on pregnancy, confinement and lactation and the mother-child relation.

Some features with which the reviewer personally takes issue are offered. In the first place, there seems to be a tendency to generalize on the subject of social stresses, which, of course, makes the text more popularly interesting, this might also be said concerning the subject of matriarchy versus patriarchy. Secondly, as in other psychoanalytic texts, the ascribing of deeper, unconscious motives for scientific investigations in social and anthropologic fields was noted. Considerable discussion could center about the difference between maternal instinct and motherliness (mother love). Dr Deutsch places emphasis on the latter almost as though it were a separate entity. To the reviewer, motherliness seems to be a more highly developed expression of maternal instinct, with volitions and inhibitions proportionately more highly developed. In this respect the psychologic expression "rich determinants of emotional motherhood" seems to be part of the entire process of adaptation to inner and outer tensions rather than a subject set apart for strictly psychoanalytic study. Another item of issue is that Dr Deutsch, throughout the text, apparently found difficulty in properly evaluating biologic and physiologic elements and sometimes verbally set them aside, only to bring them up repeatedly in connection with processes unexplainable by psychoanalytic methods. Yet considerable space was devoted to the physiology of the sexual act and organic components thereof. Still another point to be clarified is the thesis that pregnancy is often fortuitous and accidental, but that cultural actions, customs and taboos make for compensatory conscious acceptance of the fetus whereas unconscious factors may be varied and changeable, one might also question the emphasis placed on drives toward achieving motherhood.

A fuller discussion of the psychologic factors in pregnancy and motherliness in Fascist cultures, as well as more consideration of the same subject in Egyptian and Greco-Roman civilizations, would have been of greater value than the devoting of so much space to more primitive social levels and literary subjects.

Considerable positive acclaim is given to the "motherly woman," with the implication that this type of woman is the best for adjustment and mature gratifications. The reviewer again states that the book is professionally adequate, quite informative and effortless to read.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Conscience and Society. A study of the psychological prerequisites of law and order. By Ranyard West, M.D. (Lond.), D.Ph. (Oxon.) 8°, cloth, 261 pp. New York: Emerson Books, Incorporated, 1945. \$3.00.

Dr West believes that world-wide law (government and society) must be based on human nature as it is, not as prejudice makes it out to be, and that laws must be psychologically sound. The work is divided into three parts. The first is a study of human nature, including a discussion of three of its philosophies (those of Thomas Hobbes, John Locke and Jean Jacques Rousseau), human government, as viewed through the ages, the psychologic theories of human nature and the actual behavior of man. The second is a study of the control of human nature by law, comprising chapters on a psychologic theory of law and the stage of social organization represented by present international law. The third part attempts to apply present knowledge of man's social nature to present problems of social organization and world order under the headings of the emotion of loyalty and manipulation of world forces to attain world law.

Dr West is a psychoanalyst, and under the headings of psychologic theories of human nature and the actual behavior of man he devotes more than a third of his text to psychoanalysis, in which he discusses the principles of psychoanalysis, the findings of Freud in neurosis, Freud's theory of human nature (with case material) and the psychologic theories of human nature that contrast with that of Freud. The behavior of man is discussed under the headings of instinct in action, observations of child psychology, and psycho-

analytic reactions and real life side by side. This last chapter is extensively documented with case histories. The book should be useful to all persons interested in psychoanalysis.

Report of the National Health Survey. Conducted by Canadian Medical Procurement and Assignment Board. 8°, paper, 336 pp. Ottawa: Edmond Cloutier, 1945.

This extensive detailed report is divided into eight parts: civilian medical manpower, medical schools, public health, hospital personnel and facilities, industrial medicine, medical services, nursing services and dental services. Various governmental orders and statistical tables are included in a large appendix.

The Physiology of the Newborn Infant. By Clement A. Smith, M.D., professor of pediatrics, Wayne University College of Medicine, and medical director, The Children's Hospital of Michigan. 8°, cloth, 312 pp. Springfield, Illinois: Charles C. Thomas, 1945. \$5.50.

In this monograph Dr Smith considers the fetal and neonatal physiology of the child in its various aspects. He divides his subject as follows: respiration, circulatory system, blood (with a chapter on icterus neonatorum), metabolism and heat regulation, the digestive tract, nutrition, kidneys, endocrinology and immunology. The text is well documented, a lengthy list of pertinent references being appended to each chapter. The book is well printed on good paper, with a good type. This monograph should be in all medical reference collections and in the libraries of pediatricians and obstetricians.

Recent Advances in Obstetrics and Gynecology. By Aleck W. Bourne, M.A., M.B., B.Ch. (Camb.), F.R.C.S. (Eng.), F.R.C.O.G., obstetric surgeon, St. Mary's Hospital, consulting obstetric surgeon, Queen Charlotte's Hospital, and consulting surgeon, Samaritan Hospital for Women, and Leslie H. Williams, M.D., M.S. (Lond.), F.R.C.S. (Eng.), F.R.C.O.G., obstetric surgeon to out-patients, St. Mary's Hospital, consulting obstetric surgeon, Queen Charlotte's Hospital, the Jewish Maternity Hospital and the Nelson Hospital, surgeon to in-patients, Samaritan Hospital for Women, and examiner in midwifery and gynecology, University of Cambridge and Conjoint Board. Sixth edition. 12°, cloth, 357 pp., with 77 illustrations. Philadelphia: The Blakiston Company, 1945. \$5.50.

The first edition of this well known review of obstetrics and gynecology was published in 1926. Successive editions have been issued every few years to the present time. The authors were surprised to find that much valuable research had been done during the last four war years. A few entirely new chapters have been added to the present edition, namely, nutrition in pregnancy, vitamin K, stillbirth and neonatal death and erythroblastosis. There is also a new chapter on x-ray therapy in gynecology, which has been separated from the chapter on radiologic diagnosis. Certain chapters appearing in previous editions have been discarded, such as antenatal care, pyelitis, puerperal sepsis and electrophysical therapy. It should be noted that only three chapters remain from the first edition of 1926, all of which have been thoroughly revised and brought up to date. In the light of this fact, all editions of this book should be in every reference collection on obstetrics and gynecology.

NOTICES

ANNOUNCEMENTS

Dr Edward C. Dyer announces the opening of an office for the practice of pediatrics at 330 Dartmouth Street, Boston.

Dr Benjamin I. Nadelman announces his return from military service and the reopening of his office for the general practice of medicine at 140 Blue Hill Avenue, Roxbury.

Dr John A. Reidy announces the removal of his office to 1101 Beacon Street, Brookline, for the practice of orthopedic surgery.

Dr Irving Silverman announces his return from military service and resumption of the practice of pediatrics at 416 Marlborough Street, Boston.

CLINICAL MALNUTRITION IN ITALY IN 1945*

Nutritional Status of Selected Population Groups

JACK METCOFF, M.D.,† AND ANDREW J. McQUEENEY, M.D.‡

BOSTON, MASSACHUSETTS, AND BETHESDA, MARYLAND

THIS report describes a practical survey procedure for rapid clinical assessment of the nutritional status of selected population groups within a given community or area. It summarizes the results of thirty-five such studies performed in Italy during the winter, spring and summer of 1945. Approximately 4000 persons were examined. Data derived from 3109 children and pregnant or nursing women selected from refugee, institutionalized, school and population-at-large groups are presented.

By rapid, standardized assessment operations, carried out over a wide geographic area and utilizing a consistent weighted sampling technic, it was possible to gather epidemiologic information on malnutrition. This implies the determination of the extent, distribution, type and severity of existent clinical malnutrition, as evidenced by generally accepted diagnostic signs and supported by simple laboratory procedures. Data gathered in this manner were recorded on standardized punch cards, promptly analyzed and reported and used as the basis for recommendations that guided concurrent feeding operations.

GEOGRAPHIC LOCATION AND POPULATION GROUPS

Thirty-five individual nutrition surveys were performed in a wide geographic zone that included a portion of southern Italy, as well as the central and northern regions (Fig. 1).

Detailed studies were made in the Rome, Florence and Milan regions, each area had characteristic ethnic and socioeconomic differences — often accentuated by wartime alterations in transportation, housing and sanitation. Because of migration from the comparatively localized areas of destruction toward relatively intact cities, the main bulk of the population studied was urban, although several semirural and rural groups were investigated. In

each survey attention was directed toward various stress population groups in which circumstances were weighted in favor of malnutrition.

The 4000 Italians examined were composed almost exclusively of children and pregnant or nursing

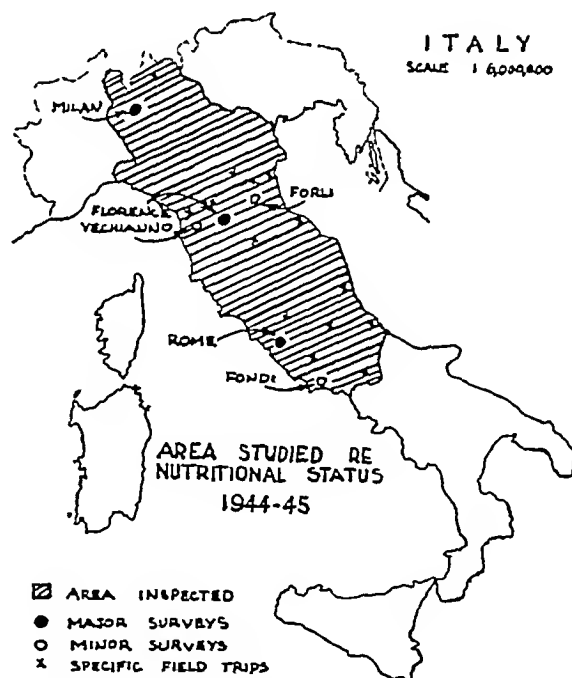

FIGURE 1 Geographic Zones Involved in Nutrition-Survey Studies

The circles represent general areas in which groups of both urban and semirural surveys were centered.

women drawn from schools, from the general population and from institutions. School children were studied in Rome, Florence, Forlì and Milan. In the same areas and in Vichiano, the general population was encountered principally within maternal and child-welfare stations. Refugee groups of dis-

*This study was carried out as part of the integrated activity of the Health Division Italian Mission, United Nations Relief and Rehabilitation Administration. Dr. D. A. Reekie, Senior Surgeon (R) USPHS, director, and the Nutrition Section, European Regional Office, United Nations Relief and Rehabilitation Administration, Dr. A. P. Meiklejohn, senior officer.

†Research fellow, Department of Nutrition, School of Public Health and Department of Biochemistry, School of Medicine, Harvard University.

‡Senior assistant surgeon (R) USPHS, Pathology Division, National Institute of Health, Bethesda, Maryland.

placed Italians were examined in the vicinity of Rome and Forlì. Institutionalized populations were drawn from state and private orphan asylums, foundling homes and penal institutions of the various areas.

METHODS OF SELECTION

The purpose of the sampling procedure employed was to obtain information regarding the nutritional status of a large population group by standardized examination of only a representative sample of the total group. True random sampling of a total population was not feasible, since the required statistics either were not available or had lost their validity, but by deliberately introducing a factor of selection in addition to the factor of chance, it was possible to modify and direct subsequent results in a predetermined and specific direction in such fashion as to disclose existent malnutrition. This, in general, was accomplished in two ways. First, in accordance with the weighted sampling procedure that Meiklejohn¹ developed in his Wales surveys, pregnant or lactating women and children who were experiencing rapid growth spurts were

served to indicate the aim and method of the study and to stimulate the necessary interest and cooperation. Specific routine questioning was designed to achieve subdivision of the area into smaller compartments, each roughly homogeneous from a socioeconomic standpoint. Within each homogeneous zone, foci of nutritional need were further localized among school, refugee or institutionalized populations on the basis of the best available data. The resultant information afforded quite reliable selection of six to eight representative examples of the neediest schools, institutions and clinics in divergent parts of the community.

Data pertaining to further definition of the population to be studied were obtained at each selected school or institution, and nominal lists of actual attendees, grouped by age or class, were inspected. An appropriate sample was attained by arbitrarily selecting from the lists each *N*th individual, *N* being determined in relation to actual attendance per age group. The sample size varied from 13 to 100 per cent of the sample eligibles (Table 1). The name, age, sex and place of origin of the selected subject

*More than 1000 cases examined in association with Unitarian Coögregational Medical Nutrition Mission at Foudi and Poitecorvo are not included.

†Eligibility depended on three factors: age groups, pregnancy or lactation and actual attendance at school or institution.

‡Includes 75 to 80 per cent of pregnant or lactating women.

deliberately selected as representing physiologic stress groups likeliest to manifest clinical evidence of malnutrition. These categories were recipients of special allowances, but it seemed unlikely that the minimal dietary supplementation would have significantly altered their status. Secondly, on the basis of carefully evaluated local information from various sources, mothers and children from poorer socioeconomic areas were chosen. It was believed that such selection would provide a heavily weighted sample representative of the worst—rather than the average—nutrition in a given area. From a physiologic standpoint, it seemed probable that if these selected groups showed little evidence of malnutrition, no significant amount of malnutrition would exist in the remaining population.

In practice, the first contacts in any urban area were with a responsible Italian official and often with the local health officer. A short conference

were inscribed by local personnel on standard punch cards. Each child or mother was then prepared for examination and queued at an appointed hour with the punch card in hand.

This general procedure was duplicated in dealing with semi-official and private organizations. In some, particularly in several refugee camps and in the general-population studies in rural or semirural areas, the procedure varied slightly. Family or dwelling units were used as the basis for area sampling within the confines of a given camp, and a total census of pregnant and nursing mothers attending maternal and child health centers in rural or semirural areas was frequently examined. In general, careful sample selection and local preparations for examination of subjects from any one area rarely required more than twenty-four to forty-eight hours, and the examination itself, rarely more than two to four hours.

EXAMINATION PROCEDURE AND REPORTING

CLINICAL CRITERIA

The basic examination procedure consisted of a rapid inspection for signs of deficiency disease: the condition of the skin of the hands, arms, legs and thorax was noted, and the eyes, nose, lips, teeth, gums, tongue, ears, neck and skeletal structures were examined. Neurologic examination was limited to observation of gait, calf and nerve tenderness in the lower extremities, when these signs were positive, reflexes and vibration sense were tested. The presence of visible, palpable thyroid enlargement and of edema was noted. Data on height and weight were collected routinely. In most cases, Sahli hemoglobin determinations, by means of earlobe punctures, were carried out on alternate subjects in the sample concerned.

It was planned to perform gravimetric copper-sulfate protein determinations² in the field, with the exception of rare cases of infantile inanition encountered in pediatric hospitals or foundling homes, however, no subjects were observed in whom plasma-protein determinations seemed clinically indicated. Consequently, protein determinations were carried out only in the rare event that pediatric hospital laboratory facilities were functioning and accessible. No satisfactory field apparatus for measuring plasma volume was available. There is laboratory evidence that determination of plasma-protein concentration, without concomitant plasma-volume measurement, yields misleading and equivocal data, particularly in protein deficiency states.^{3, 4}

Except for infants, patients were only partially disrobed. The thorax and abdomen of mothers were not examined routinely. Two physicians alternated in the performance of clinical examinations and Sahli hemoglobin determinations. A relatively high degree of similarity in technic and diagnosis was attained by both observers. Diagnoses were recorded by means of a moderately complete, systematized numerical code that involved approximately one hundred and twenty clinical signs of deficiency disease, the numbers of which had been printed on the standard survey cards.⁵ After short experience, code numbers of the majority of signs were easily recalled. During the course of the examination, numbers on a given patient's card corresponding to observed signs were circled by an assistant. This method of recording observations was found to be quite efficient in minimizing friction, error and delay. Recording of hemoglobin levels in terms of fairly broad ranges contributed to ease in performance and subsequent analysis.

On completion of a survey, the card of each subject was punched in accordance with the numbers circled on it. All cards were sorted, and the data transcribed on detailed standard work sheets, analyzed and reported, usually within twenty-four to forty-eight hours after completion of the survey.

Since various biochemical lesions of mild deficiency states cannot be readily and conclusively detected at a clinical level without associated laboratory aids,⁶ the categorization of malnutrition was restricted to classic deficiency disease. There are considerable variations in the criteria used for such diagnoses, but in these studies the following were required.

Rickets All subjects had at least three skeletal signs of rickets, including marked frontoparietal bossing with or without craniotabes, Harrison's groove, marked enlargement of costochondral junctions (so-called "beading" or "rosary"), clinically enlarged epiphyses or deformity of the long bones — the last being defined as deformity of lower extremities of such a degree that the distance between malleoli at proximal or distal ends of the tibiae was 3 cm or more. No roentgenographic or laboratory facilities for corroborative diagnosis or for determination and assessment of rachitic activity were available. Consequently all rickets in children four years of age or over was diagnosed as inactive or old, rickets in younger children was arbitrarily called active or recent on the basis of physiologic and statistical chance.^{7, 8}

Ariboflavinosis All cases so diagnosed had cheilosis, that is, angular stomatitis associated with denudation with or without fissuring of the lower lip, magenta tongue with fungiform hypertrophy and sometimes classic nasomalar seborrheic dermatosis. Circumlimbal injection was noted but was not considered in the diagnosis.

Vitamin A deficiency All cases so categorized were observed in subjects with lackluster dryness of the conjunctivas and moderate or marked conjunctival thickening (excluding pterygia and pingueculas), with or without Bitot's spots, as well as typical keratosis follicularis of both upper and lower extremities. Acneform and impetiginous skin lesions were noted but were not requisite for the diagnosis.

Inanition In all such cases there were obvious loss of subcutaneous tissue, dehydration, loss of turgor with looseness and wrinkling of the skin, prominent bones and protuberant abdomen, with associated growth retardation or weight loss. The inclusive term "inanition" as applied, therefore, is synonymous with marasmus, infantile dystrophy, infantile atrophy and so forth.

Anemia This diagnosis was arbitrarily designated when Sahli hemoglobin levels of 8 gm per 100 cc. or less in infants under two years of age and 10 gm per 100 cc. or less in children and in adults were observed — normal hemoglobin values for infants under two years of age are approximately 1 or 2 gm less than those for older children and adults.⁹⁻¹¹ These arbitrary levels probably repre-

sented moderately severe anemia, although the range of normal variation is apparently large⁹⁻¹². The standard for the instrument used was 14.6 to 15.6 gm per 100 cc.

Other diseases No lesions typical or strongly suggesting pellagra, beriberi, scurvy or hypoproteinemia were observed*. Associated or conditioning diseases were recorded when evident or when adequate data were available.

RESULTS

Rickets was the most frequent classic deficiency disease observed. The incidence in particular surveys varied from 25 to 30 per cent among school children to 60 per cent among younger children and institutionalized infants. The overall incidence of rickets in the total sample was 27.7 per cent and proportionally equal in the groups over and under four years of age. This overall incidence is somewhat lower than that observed by Follis, Jackson, Eliot and Park¹³ among children of Italian descent in their hospital-population study, although such a comparison is not entirely valid, since the method of diagnosis differed.

Although suggestive signs of ariboflavinosis were often noted among children three to twelve years of age, diagnostic clinical cases were rarely encountered, the incidence varying by surveys from 0 to 2 per cent.

Suggestive signs of vitamin A deficiency were noted occasionally, the incidence of keratosis follicularis, for example, varied by areas from 0 to 22 per cent. No keratomalacia was observed, although the regional occurrence of eye diseases ascribed by Italian physicians to vitamin A deficiency was apparently not infrequent in the prewar years^{14, 15}. The general incidence of clinical vitamin A deficiency approximated 1.5 per cent.

Inanition, noted only among refugee or institutionalized infants two years of age and under, was frequently conditioned by a previous or current infectious process, and was often independent of available food supply. Approximately 3.0 to 7.0 per cent of institutionalized infants were classified as showing inanition — an incidence of 0.7 per cent in the total child population studied. Among the same groups of infants two years of age and under and in some groups of institutionalized preschool children, height and weight values were not infrequently below those for the national average, this might have been anticipated in view of the weighted sampling procedure employed. Neither inanition nor significant degrees of growth retardation were demonstrable among other groups of children studied.

With the exception of the previously mentioned data on institutionalized infants and young children, the 80 percentile range and median values for height

and weight of central and northern Italian preschool and school-age children showed no marked deviations from prewar Italian standards¹⁶.

The incidence of moderately severe anemia varied from 3.0 to 20.0 per cent among institutionalized infants and preschool children, but was only 0.3 per cent among school children and 1.5 per cent among pregnant and lactating women. Since procedures other than hemoglobin determinations were not attempted under existing field conditions, it is quite possible that some of the cases of anemia observed were of non-nutritional origin.

Simple diffuse thyroid enlargement was noted in 5 to 9 per cent of children and in 18 to 23 per cent of pregnant and nursing women. In some samples the incidence of such enlargement in children under ten years of age approached 9 or 10 per cent. The geographic distribution of this finding was fairly uniform. No cases of hyperthyroidism or hypothyroidism and no cretins were seen. The association between thyroid enlargement and fluorosis was not investigated but was observed particularly in Campagna da Roma, where endemic dental fluorosis is almost universal among the static population.

Completely negative examinations were rare (2.0 to 4.5 per cent), and many isolated signs but no other classic deficiency diseases were observed. Gross psychologic or psychomotor alterations, such as apathy, listlessness, excessive irritability, anxiety and depression, were not particularly apparent.

Data pertaining to the incidence of deficiency signs and diagnoses are recorded in Tables 2, 3, 4, 5 and 6.

With the exception of inanition and infantile anemia there was little significant difference in the occurrence of classic deficiency disease in the various population categories of the respective age and sex groups.

DISCUSSION

In thirty-five surveys involving widely scattered stress population groups totaling approximately 4000 subjects, it was not possible to demonstrate any gross clinical malnutrition serious enough in degree or wide enough in distribution to constitute an acute relief feeding problem. With rare exceptions, no deficiencies were encountered that could not have been prevented or successfully treated with cod-liver oil or dry skimmed milk, as well as timely and intelligent pediatric care.

In all surveys such deficiency disease as was encountered consistently followed a fairly uniform pattern indicative of mild chronic or subacute malnutrition. Minor regional differences in the severity of lesions were noted, but the basic pattern of deficiency showed relatively little variation. The mildness and uniformity of the nutritional deficiencies are not particularly surprising when general approximate food consumption, based on budgetary-analysis data gathered by competent workers (Table 7) is considered¹⁷⁻¹⁹.

*Gingivitis was not considered to be of scorbutic origin unless edema, cyanosis, retraction, loss of interdental papillae and bleeding were associated findings. Nonspecific glossitis was noted and described but was not interpreted in relation to any specific deficiency.

*Data based on studies and analyses of weekly food consumption carried out by trained and experienced workers

The principal Italian dietary alterations associated with war appear to be reduction in dietary fat and carbohydrate, with relative caloric diminution in recent diets. The popularly reported caloric inadequacy of the 1944-1945 Italian ration (900 to 1400 calories) should be interpreted with the realization that approximately only 12 per cent of a person's usual food consumption was derived from ration-card sources, and only about 5 per cent of the weekly food expenditure was utilized for the

of fertilizer, land mining and political flux on present and future crop production is unpredictable, and the accurate assessment of national food reserves is exceedingly difficult.

The high incidence of clinical rickets—277 per cent—is of some interest. Cod-liver oil and concentrated vitamin D preparations were either in short supply or used for therapeutics rather than prophylaxis. Children were often placed in the vicinity of the sun rather than in direct exposure

FIGURE 2 Median Values for Heights and Weights of Central (Rome Area) Italian Children of School and Population-at-Large Groups

The values (black dots) are superimposed on charts indicating the 80 percentile ranges for height and weight of normal American children derived from the data of Vickers and Stuart.²⁴ Heights were measured in bare or stockinged feet, and weights in light underclothing, ages were taken to the nearest birthday. Data applicable to 231 institutionalized children in the Rome area were not included. Of these, the medians and 80 percentile ranges of 61 males of four, five and six years of age and 36 females of four and five years of age were consistently lower than the medians charted.

purchase of rationed food.¹⁹ Seventy-five to 90 per cent of the weekly food expenditure was used for purchase of free or black-market foods. In most areas communal restaurants provided calorically adequate, low-cost meals for families in the lower economic bracket. In Milan, for example, approximately two thousand restaurants provided 600,000 persons with daily meals at a usual rate of 4 to 50 lire per meal. Food was usually available, but there is little doubt that the inflationary economy imposed a severe economic burden on fixed-income groups. The effect of such factors as drought, lack

to its rays—a practice that apparently originated from the experience that direct exposure of infants to the spring or summer sun occasionally induced "convulsions and death." In addition, it is quite possible that dietary calcium intake was inadequate, since the relatively low milk and dairy-product consumption^{17, 20} had been further reduced by war. Irrespective of these conditioning factors, the existence and maintenance of numerous hospitals for the treatment of rachitic deformities in children suggest that for generations clinical rickets has been widespread in

school, and population-at-large groups suggests that gross malnutrition was infrequent, that rickets was the only nutritional problem of public-health importance, that there was no conclusive evidence — on the basis of observed deficiencies or growth retardation — that wartime food shortage constituted a major health problem, and that the reported data could probably be duplicated in many areas of the

FIGURE 4 Heights and Weights of Italian Infants Compared with Prewar Italian and American Standards. Infants were examined and measured nude. The height represents recumbent length. Because of the weighted sampling technique employed in all surveys, the height-weight values fall consistently below mean prewar values. The trends of both curves are essentially the same. If samples had been weighted in the opposite direction, height-weight values obtained would be expected to fall at approximately the 80 percentile level of a normal distribution curve.

United States if the same method of sampling were employed.

We are indebted to Dr R E Butler, Senior Surgeon, USPHS, and to Dr A P Meiklejohn for their active interest and field sponsorship of this investigation. The technical assistance of Miss Amalia Baran was invaluable, as was the kind co-operation of many Italian physicians, nurses and government officials. Figures 2 and 3 were devised and furnished by Dr Harold Stuart, of the Harvard School of Public Health.

NONTRAUMATIC SPONTANEOUS PNEUMOTHORAX AMONG MILITARY PERSONNEL*

MAJOR SAMUEL COHEN, M C, A U S, AND LIEUTENANT COLONEL J MURRAY KINSMAN, M C, A U S

THIS study was undertaken with the main purpose of determining the etiologic background and the precipitating factors in cases of nontraumatic spontaneous pneumothorax among hospitalized military personnel. Records covering a ten-year period were reviewed. In the six-year interval from January, 1935, to December, 1940, inclusive, when the military strength of the post was relatively low, there were no cases of spontaneous pneumothorax. In the succeeding four years (January, 1941, to December, 1944, inclusive) 41 cases were encountered. The pertinent military, clinical and roentgenologic aspects are presented and discussed.

MILITARY DATA

The incidence of spontaneous pneumothorax for the years 1942 through 1944, based on the annual hospital admissions of military personnel, was practically constant 0.027 to 0.03 per cent (Table 1). These figures are not valid for comparison

TABLE 1 Incidence of Spontaneous Pneumothorax among Military Personnel

YEAR	NO OF HOSPITAL ADMISSIONS	CASES OF SPONTANEOUS PNEUMOTHORAX	
		NO	PERCENTAGE
1941	48,527	1	0.002
1942	52,947	16	0.03
1943	51,339	14	0.027
1944	52,765	10	0.027

with statistics from civilian institutions, since many soldiers were admitted for conditions that would not necessitate hospitalization in civil life.

The onset of the pneumothorax ranged from four days to eighteen years after entrance into the Army, and the average length of hospitalization was forty-one days. Twenty-nine soldiers were returned to full duty and 4 to limited duty—a total of 80 per cent. Three patients were transferred to a general hospital, 2 because of failure of the lung to re-expand and 1 (an officer) because of recurrent spontaneous pneumothorax. One enlisted man was separated from the service because of a history of multiple episodes of spontaneous collapse of the lung. Two soldiers were discharged because of an associated psychoneurosis. There were 2 patients with far advanced pulmonary tuberculosis, one of whom died, and the other was transferred to a Veterans Administration hospital.

*From the Medical Service Regional Hospital, Fort Bragg, North Carolina.

CLINICAL FEATURES

The remainder of this report is based on 39 patients in whom sufficient clinical and roentgenologic data were available for study (Table 2). All were men, and the average age was twenty-four years and ten months. Four soldiers, or 10 per cent, gave a history of an antecedent spontaneous pneumothorax, in only 1 did the recurrence develop in the military service.

Symptoms

It is logical to assume that the intensity of the initial pulmonary symptoms depends on the size of the rupture, the presence or absence of adhesions or fluid, or both, and the type of pneumothorax—whether closed, open or valvular. The onset was sudden in all but 1 case. Shortness of breath, which was a complaint of all patients, was objectively present in comparatively few. Chest pain, of varying severity, occurred in every patient, and the pain was most frequently localized over the affected lung but sometimes radiated to the shoulder, neck, lower back or abdomen. Cough was present in 7 soldiers, cyanosis in 3, mild collapse in 3, and fever in 2 (active pulmonary tuberculosis).

The relation between physical exertion and the production of a spontaneous pneumothorax is not only of medical interest but also of practical importance from a military viewpoint. The following circumstances at the time of onset were studied (in 1 case an adequate history was not available).

At ease or at rest. It is significant that, in 23 cases (59 per cent), the episode could not be associated with any provoking cause.

Physical effort not specifically related to military activity. Ten soldiers, or 26 per cent, were classified in this group. The exertion was mild (walking).

Physical effort directly related to military activity. Five soldiers, or 13 per cent, gave a history of such exertion immediately prior to collapse of the lung. The military duties performed at the time were as follows: hauling sand, kitchen police, with lifting of heavy utensils, shoveling dirt, running over the obstacle course, and drilling troops.

Physical Signs

The classic signs of air in the pleural cavity are well known. Their prominence depends on the extent of pulmonary collapse and of mobility of the mediastinum. The most constant single sign recorded was diminished or absent breath sounds over the pneumothorax pocket. In all cases, the spontaneous pneumothorax was unilateral. The

lungs were almost equally affected the right in 54 and the left in 46 per cent. None of the patients showed subcutaneous or mediastinal emphysema.

Tuberculin Test

This simple and valuable test was performed in only 12 cases (excluding the 2 patients with active tuberculosis). A positive reaction does not necessarily indicate clinical tuberculosis, but a

these presented no pulmonary lesion on the x-ray film, 2 showed calcified, first-infection-type tuberculosis, and 1, a calcified primary complex with slight linear productive apical infiltration.

ROENTGENOLOGIC FEATURES

Roentgenography of the chest is the most reliable method of diagnosis of pneumothorax. A

negative test virtually excludes this diagnosis, provided that there are none of the conditions that would depress the allergic response. Six of the 12 soldiers were positive reactors. Three of

film taken at the end of forced expiration is especially valuable in detecting a small collection of air in the pleural space. The findings (Table 2) can be summarized as follows:

Pulmonary Disease

Active, far advanced pulmonary tuberculosis (positive sputum) was found in 2 patients (5 per cent), 1 of whom had a right-sided acute bronchopneumonic process on admission and subsequently developed a spontaneous pneumothorax, with a persistent bronchopleural fistula. The lung showed

right side, and ten days before death a spontaneous collapse developed on the left. The left lung, at autopsy, presented miliary and conglomerate tubercles, caseous foci of varying size, multiple cavities and, in addition, several small, thin-walled emphysematous blebs at the apex. It was the opinion of the pathologist that the spontaneous pneumothorax was due to the rupture of an emphy-

only slight re-expansion three months later, when the patient was transferred to a Veterans Administration hospital. The second soldier had bilateral tuberculosis, with cavitation and bronchogenic spread. Artificial pneumothorax was induced on the

sematous bleb (one bleb was found open), rather than to a perforating tuberculous lesion.

Inactive, minimal pulmonary tuberculosis (negative sputum) was present in 3 cases, or 8 per cent. In all, the roentgenogram showed unilateral apical

linear productive infiltration. The films also revealed a calcified primary complex in 2 cases, in 1 of which the spontaneous collapse was on the side opposite the reinfection infiltrate. These were the pulmonary findings on admission, and nothing new was noted after re-expansion of the involved lung.

Calcified, primary infection-type tuberculosis only was observed in 4 cases (10 per cent), in 3 of which the pneumothorax occurred on the same side. Again, re-expansion showed no other foci.

No pulmonary process could be demonstrated in 30 cases, or 77 per cent. In 28 cases there was no evidence of pulmonary disease or of emphysematous blebs or bullae after total re-expansion, 2 soldiers were transferred to a general hospital after observation for twenty-seven days in 1 and fifty-four days in the other had failed to reveal significant pulmonary re-expansion, although the visualized lungs were clear.

Extent of Pulmonary Collapse

In the initial roentgenogram taken at the end of inspiration the collapse was considered mild (5 to 25 per cent) in 51 per cent, moderate (30 to 45 per cent) in 26 per cent and marked (50 per cent or more) in 23 per cent of the cases, in the last group x-ray films after re-expansion were negative in 6 cases, 2 showed a healed primary lesion, and 1 revealed active tuberculosis.

Pleural-Fluid Formation

No fluid was observed in 65 per cent, a tiny amount covering the costophrenic angle in 25 per cent, and a small effusion up to the tenth posterior rib in 10 per cent of cases. The 2 soldiers with active tuberculosis, as well as 2 with a calcified first infection, were in this last category. The fluid completely resorbed in all but the 2 soldiers with active tuberculosis.

Adhesions

Adhesions were noted in 13 per cent of cases. Two patients presented no pulmonary lesion after re-expansion, 1 had active tuberculosis, and the remaining 2 had inactive minimal tuberculosis.

TREATMENT

All patients received bed rest, partial or complete. Symptomatic medication to allay apprehensiveness and cough was administered to some. Aspiration of air from the pleural cavity to relieve dyspnea was performed in 3 soldiers, 2 of whom had active pulmonary tuberculosis, these 2 patients were the only ones who also needed oxygen.

DISCUSSION

The problem presented by nontraumatic spontaneous pneumothorax in the Army is not an insignificant one. The important features to be

evaluated are etiology, therapy and military disposition.

Etiology

The immediate cause of spontaneous pneumothorax is a tear of the visceral pleura and the subjacent lung. Many pathologic conditions, however, are responsible for nontraumatic pulmonary collapse. To enumerate them would be superfluous. The chief diagnostic problem is the determination of the presence or absence of tuberculosis as the etiologic agent. It is the consensus that, of the various pulmonary afflictions, tuberculosis is the most frequent. On the basis of autopsy reports, about 10 per cent of patients develop this complication in the course of the disease.¹ The highest incidence is in the actively progressing lesions in which a subpleural cavity or caseous focus, which is free of overlying adhesions, erodes into the pleural cavity. The tearing of adhesions at the base of a necrotic lesion also initiates spontaneous pneumothorax. Furthermore, subpleural emphysematous blebs with rupture may develop, especially in conjunction with fibrotic tuberculous lesions. Their co-existence in a given patient renders evaluation of the precipitating factor difficult.

During the last two decades particularly, with the increasing use of chest x-ray examinations, many cases of spontaneous pneumothorax have been detected in apparently healthy persons with no symptoms, signs or roentgenographic evidence of tuberculosis or other pulmonary disease. Most cases have been observed in young men. The causative association, in the great majority of cases, between a so-called "idiopathic pleural effusion" and tuberculosis is still valid. Although the possible existence of a small subpleural tuberculous focus that is not demonstrable by roentgenography may be the source of a pneumothorax, accumulated data indicate that the old conception of the rigid relation between spontaneous pneumothorax and tuberculosis needs revision. Essential, idiopathic and primary spontaneous pneumothorax are terms that are designated as the pneumothorax of apparently healthy persons. Obviously, every case in which such a diagnosis is made should be carefully studied during and after complete re-expansion of the lung to rule out tuberculosis. If the disease has been excluded at the time, the patient is no likelier to develop tuberculosis later than the average person. Kjaergaard² observed only 1 case in a follow-up study of 49 patients after a two-year period. Perry,³ who re-examined 55 out of 85 patients without finding a single case of tuberculosis, stated that in 250 cases mentioned in the literature that were checked for several years only 6 patients had tuberculosis.

In our clinical material, 28 patients, or 72 per cent, definitely showed no clinical or roentgenologic evidence of tuberculosis either of the first or re-

infection type, and they can be grouped as cases of primary spontaneous pneumothorax. In 1943, among the Army population in the continental United States, there were 873 hospital admissions for this condition.⁴ The average hospitalization period was forty days. Approximately 15 per cent of the soldiers were separated from the service, and the remainder were returned to general or limited duty. Our figures conform closely to these. The most reliable criteria in differentiating a simple primary from a tuberculous spontaneous pneumothorax are negative clinical and roentgenologic evidence of tuberculosis, a negative tuberculin test, absence of adhesions, little or no fluid, absence of fever and prompt recovery with fairly rapid re-expansion of the lung.

The pathogenesis of primary spontaneous pneumothorax is explained on the basis of one of three main conditions or mechanisms.

Congenital cystic disease of lungs. There may be congenital maldevelopment of the bronchi and cystlike pulmonary anomalies. One or more of the cystlike dilatations may rupture and produce spontaneous pneumothorax.⁵

Rupture of subpleural emphysematous blebs. The most frequent site for these blebs is in the apexes and upper anterior margins of the lungs. The theory has been advanced that under conditions of increased intrathoracic pressure, such as that produced by coughing and sneezing, with the glottis closed, air is forced from the bases of the lungs into the apexes because of the less rigid nature of that portion of the chest wall.⁶ The process of repeated distention of the apexes ultimately causes a rupture of the elastic fibers in the walls of peripherally located alveoli. Air then escapes into the alveolar layer of the pleura, which becomes raised and separated from the alveoli. The air dissects itself along the pleura and is finally intercepted by the lobular septums. The mere presence of emphysematous blebs, however, does not necessarily augur the development of spontaneous pneumothorax. Positive autopsy evidence of blebs is often found in patients with a negative clinical history of spontaneous pneumothorax. This accident is attributed to a check-valve mechanism, which permits easy ingress but difficult egress of air from the subpleural bleb, so that the bleb becomes distended and thin walled and finally ruptures, with or without an element of physical exertion. Roentgenographic examination sometimes demonstrates in large blebs or vesicles a fluid level that constitutes indirect evidence of a check valve. Furthermore, at post-mortem examination, the air cannot readily be expressed from some blebs, whereas in others the procedure is comparatively easy. The check valve manifests itself as an expiratory obstructive mechanism in the form of inspissated exudate, scar tissue in

the region of the bleb and the adjacent bronchiole (Kjaergaard⁷ reported such a finding at autopsy in 2 nontuberculous patients) or openings between the bleb and the communicating narrowed alveoli that may be of different sizes.⁸ Emphysematous blebs are sometimes seen in the roentgenograms of the chest, usually in the apexes, and appear as thin-walled ring shadows that simulate tuberculous or bronchiectatic cavities. The absence of surrounding reaction and the lack of clinical symptoms and signs constitute the chief differential features. It should also be stated that thoracoscopy — direct inspection of the pleural cavity in the presence of pneumothorax — may reveal emphysematous vesicles, the best objective ante-mortem evidence is furnished by this procedure.

Rupture of interstitial emphysematous blebs. McGuire and Bean,⁹ Hamman¹⁰ and Macklin¹¹ believe that this is a plausible mechanism. Macklin, in experimental animal studies, found that by increasing the intrapulmonary pressure, air escapes from small ruptures in the walls of alveoli or bronchioles and then traverses the perivascular sheaths through the interstitial tissue to the root of the lung, where it pierces the mediastinum and produces spontaneous mediastinal emphysema, dissects along the fascial planes in an upward or downward direction, or both, — and thus causes a more or less generalized emphysema, — or extends to the pleura forming a bleb that ruptures. Miller¹² recently described 4 cases of spontaneous mediastinal emphysema, 2 of which were associated with a pneumothorax. The simultaneous bilateral spontaneous pneumothorax that occurs in some idiopathic cases is probably due to a rupture in the portion of the posterior mediastinum, between the esophagus and aorta, in which the two layers of mediastinal pleura are in contact. Macklin and Macklin¹³ suggest that there may be a constitutional or hereditary factor — an inherent weakness of the alveoli and the pleura — which predisposes to rupture. In support of this hypothesis, they refer to reported cases of spontaneous pneumothorax occurring in the same families, in most of whom there was no demonstrable pulmonary pathology, tuberculous or otherwise, to account for the pneumothorax.

Therapy

Additional remarks on treatment are pertinent.

The immediate treatment of spontaneous tuberculous pneumothorax consists in complete bed rest, relief of shock, if present, symptomatic medication for cough, nervousness and so forth, aspiration of air or fluid, or both, from the pleural cavity to relieve cardiac or respiratory distress and oxygen therapy. A spontaneous pneumothorax should be converted into a therapeutic pneumothorax if the underlying pulmonary disease warrants its mainte-

nance If, after a reasonable period, the affected lung shows little or no tendency to re-expand, the possibility of a bronchopleural fistula should be investigated This condition was present in one of our tuberculous patients with a tension pneumothorax, and underwater drainage was instituted, with considerable relief of dyspnea

Most patients with primary spontaneous pneumothorax require no treatment except partial or complete bed rest for a few weeks Symptomatic treatment, oxygen therapy and aspiration of air are applicable when indicated The immediate prognosis in unilateral cases is excellent Recurrent pneumothorax is not infrequent, however Its incidence, of course, depends to some extent on the length of the follow-up period of observation Four of our cases, or 10 per cent, were recurrences Wilson¹⁴ reported 20 per cent, and Ornstein and Lercher⁶ 30 per cent Recurrences in any given patient cannot be foretold in advance and cannot be prevented except by the obliteration of the pleural space by adhesions This can be artificially produced, but should not be undertaken after the first episode of spontaneous pneumothorax because the majority of patients suffer only one attack, following which they engage in moderate or strenuous exertion for years with no recurrence Waring¹⁵ discusses the problem of inducing a chemical pleuritis, by the injection into the pleural cavity of an irritant, such as sterile mineral oil or Gomenol, to create pleural synphysis

Military Disposition

The disposition, which is not always uniform for any given condition, varies with Army directives, the medical installation in which hospitalization occurs, the particular type of duty performed by the soldier and so forth The disposition of patients with nontraumatic spontaneous pneumothorax from a medical point of view depends largely on the etiologic diagnosis Patients with cases secondary to pulmonary tuberculosis (reinfection type) should be discharged from the service

In primary spontaneous pneumothorax, the underlying pathologic process is benign Whether the exertion of military duties is an increased hazard remains an open question A history of strenuous physical effort, as an exciting cause, is lacking in many cases It would be interesting to obtain data on the comparative incidence of primary spontaneous pneumothorax and its correlation with physical activity among civilians and military personnel of the same age groups The chief precautionary measure for these patients is the avoidance of exertion, coughing or straining with a closed glottis, which increase intrapulmonary pressure and may precipitate a spontaneous pneumothorax, provided the appropriate anatomic background exists Holter and Horwitz¹⁶ also cautioned against airplane travel for persons with a diseased pleura

They reported a case in which the spontaneous pneumothorax was interpreted as being due to the change in atmospheric pressure by ascent to 8000 feet They believed that the fall in pressure from 760 to 560 mm of mercury increased the tendency for pulmonary collapse, exploited a pleural weakness (emphysematous bleb) and produced a spontaneous pneumothorax This conclusion was disputed by Engel and Ferris,¹⁷ who in commenting on the case report, stated that the pneumothorax existed prior to or was coincidental to the flight rather than being caused by it, and that the reduction in barometric pressure is transmitted equally and promptly to all body tissues so that the ratio between the intrapulmonary and intrapleural pressures remains the same Their explanation was as follows

Changes in pressure and volume will occur only in gas containing structures that have inadequate or no communication with the external atmosphere (i.e., middle ear, paranasal sinuses, gastrointestinal tract) As long as there is no air in the pleural space there will be no relative change in intrapulmonary pressure and hence no tendency for the lung to collapse partially Similarly an emphysematous bleb would not be any more likely to rupture at altitude unless it had little or no communication with intrapulmonary air

Probably the most frequently recommended military disposition is reclassification of the soldier to limited duty after an episode of unilateral primary spontaneous pneumothorax and separation from the Army for patients with recurrent unilateral or simultaneous bilateral collapse This policy has not been consistently followed at this installation

SUMMARY AND CONCLUSIONS

Forty-one soldiers with nontraumatic spontaneous pneumothorax were admitted to a large army hospital during a four-year period (1941-1944) The pertinent military data concerning the incidence, length of service and hospitalization and disposition are presented

In 39 cases there was sufficient information for evaluation of the clinical and roentgenologic aspects The most important single clinical feature was the correlation between physical exertion and pneumothorax, in 60 per cent of the cases the episode was unassociated with exertion, in 26 per cent physical effort was mild and not related to military activity, and in 13 per cent exertion was severe and linked directly to military duties The main roentgenologic observation was the presence of underlying active pulmonary tuberculosis in 5 per cent, inactive reinfection disease in 76 per cent, calcified primary infection in 10 per cent and no parenchymal disease in 77 per cent of the cases

Primary spontaneous pneumothorax is the pneumothorax of apparently healthy persons with no clinical or roentgenologic evidence of pulmonary disease Its pathogenesis may be due to rupture of a congenital pulmonary cyst or to a subpleural

or interstitial emphysematous bleb. The differential diagnostic criteria and the therapeutic measures in tuberculous and primary spontaneous pneumothorax are briefly discussed.

The military disposition depends largely on the etiologic diagnosis. Soldiers with pulmonary collapse attributable to tuberculosis (reinfection type) should be discharged from the Army. Primary spontaneous pneumothorax is benign. The disposition most frequently recommended is reclassification to limited military duty following an attack of pulmonary collapse and separation from the service following simultaneous bilateral or recurrent unilateral episodes.

PLASMA ALPHA AMINO NITROGEN LEVELS IN PATIENTS WITH THERMAL BURNS*

S M LEVENSON, M D,† M A ADAMS, A B,‡ R W GREEN, M D,§ C C LUND, M D,¶ AND F H L TAYLOR, M Sc, Ph D||

BOSTON

INCREASES in the concentration of plasma amino acids following burns have been reported by Glenn, Muus and Drinker¹ in calves, and by Harkins and Long² in rats. The present communication reports a study of the plasma alpha amino nitrogen concentration in human beings with extensive burns.

METHODS

Twelve patients with severe burns admitted to the Boston City Hospital during the period 1943 to 1945 were studied. The essential details are summarized in Table 1. The area of burn was estimated by the method of Lund and Browder,³ and the depth of burn classified according to the method of Converse and Robb-Smith.⁴ These authors classify the depth of burn by name instead of by degree, using the terms "epidermal" for burns with erythema only, "dermal" and "deep dermal" for superficial and deep injury of the derma without complete destruction, and "deep" for burns with complete destruction of all epithelial elements. In this study the area of

epidermal burn was disregarded. The depth of burn cannot be determined with accuracy in patients who survive for only a few days, and consequently can only be approximated. The local treatment was dry, sterile, pressure dressings with no preliminary cleansing. Anesthesia was not given, the dressings being done under mild morphine sedation.

The alpha amino nitrogen concentration was determined by the ninhydrin method of Van Slyke.^{5,6} The determinations were usually made on plasma and occasionally on serum, care being taken to avoid delay in separation of the blood cells.

A preliminary study of the method was made on fifty blood samples from 9 normal persons. The mean value for all determinations was 3.6 mg of alpha amino nitrogen per 100 cc of plasma, with a standard deviation of 0.36 mg from the mean. The criterion for significant elevations over normal in the patients under study was a concentration of alpha amino nitrogen at least three times the standard deviation above the normal mean value — that is, a level of 4.7 mg of alpha amino nitrogen per 100 cc of plasma was considered significantly elevated.

All the patients received homologous plasma in amounts varying from 0.5 to 6.5 liters during the first forty-eight hours. To rule out the possible effects of plasma administration on alpha amino nitrogen concentration in the plasma, 2 normal subjects were given 1.5 liters of two-year-old liquid plasma in the course of two hours. Serial determina-

tions of plasma alpha amino nitrogen concentrations before, during and at hourly intervals after the administration of plasma showed no significant changes.

Hemoglobinemia was found in almost all samples during the first twenty-four hours. About 15 per cent of the circulating red blood cells, however,

fall in the plasma alpha amino nitrogen concentration below normal. In contrast, 8 of the 12 patients showed a significant elevation of the plasma or serum alpha amino nitrogen concentration in the first twenty-four hours following injury. Seven of these 8 patients had burns, chiefly deep, involving over 35 per cent of the body surface, whereas 1 (Case 1)

would have had to have been destroyed to account for a rise of the plasma alpha amino nitrogen concentration to the levels considered significantly elevated in this communication. Hemolysis of such a degree did not occur.

RESULTS

The over-all data obtained in the 12 patients are listed in Table 1. In no case was there a significant

had 15 per cent of the body surface burned. The elevation of the plasma alpha amino nitrogen concentration in this last case was transitory and not so great as that in the others.

Clinical shock was present in varying degrees in 7 of the 8 patients. Four of these patients had marked hypotension on entry, and in all the plasma alpha amino nitrogen concentration was elevated at that time. In the other 3 patients hypotension occurred

four, eleven and a half and twenty-two hours, respectively, after entry, in the last 2 patients the plasma alpha amino nitrogen concentration was elevated before the period of hypotension, whereas in the other the elevation occurred for the first time at the time of hypotension. In four patients the level remained high for varying lengths of time after the shock had been successfully treated.

There were 4 patients with no significant elevation of the plasma or serum alpha amino nitrogen concentration, 3 of whom had no shock at any time. The extent of burn was 20 per cent in 2 of these patients and 40 per cent in the other. Another patient, an eight-year-old girl, was severely burned, 50 per

hours after injury, at about which level it remained until death on the third day. Icterus indexes in the other patients in the twenty-four hours after entry were unsatisfactory because of the presence of hemoglobinemia. Later determinations were available only in 1 patient (Case 1) with an elevation of the plasma alpha amino nitrogen, and were normal. Icterus indexes were also normal in the 4 patients who had no significant elevation of the plasma alpha amino nitrogen concentration.

The quick prothrombin time was prolonged in 4 of the 5 patients with elevated plasma or serum alpha amino nitrogen concentration on whom the determinations were made, but were not significantly

FIGURE 1 Case 6

cent of the body surface being involved. Shock was severe on entry but thereafter was minimal or absent.

In the 8 patients with significant elevation of the plasma alpha amino nitrogen concentration, 7 showed an elevation of the nonprotein nitrogen of the plasma above 35 mg per 100 cc. Oliguria was usually present in these cases. In all but 1 patient, however, the rise in the alpha amino nitrogen concentration was observed at times when the nonprotein nitrogen concentration in the blood was still normal. Hemoconcentration was present in almost all the 12 cases but was more marked in the 8 patients with increased alpha amino nitrogen concentrations.

No patient in this series had a history or physical signs of liver or renal disease. One patient (Case 9) was a morphine addict. The icterus index in this patient was 10 on entry and rose to 25 within seven

prolonged in 3 patients with no significant elevation of the plasma alpha amino nitrogen.

Post-mortem examinations were performed on 5 patients who had had significant elevations of plasma alpha amino nitrogen concentration and on 2 who had not. In no case were significant hepatic morphologic changes found.

The following case reports typify the findings in the group of patients showing an increased plasma alpha amino nitrogen concentration.

CASE 6 L. A., a 29-year-old man with a noncontributory history, sustained flame and electric burns and some damage to the respiratory tract shortly before entry. Thirty-five per cent of the body surface was involved in mixed dermal and deep burns, chiefly the latter. The data are presented in Figure 1.

Examination on entry revealed a well developed and well nourished man. The blood pressure was 130/70, the pulse 100 and of good quality, and the respirations 25. The hemo-

globin was 141 per cent, and the alpha amino nitrogen concentration 4.2 mg per 100 cc of plasma.

During the next 3 hours small amounts of water were administered orally, no other fluids being given. The patient gradually went into profound circulatory collapse, no blood pressure or pulse being obtainable for the last half hour of this period. The extremities were cold, clammy and cyanotic. There had been no output of urine. The hemoglobin had risen to 172 per cent, whereas the plasma alpha amino nitrogen concentration had risen slightly — to 4.8 mg per 100 cc. Administration of plasma was then begun, and during the next 2 hours the systolic blood pressure was kept between 80 and 90 and was thereafter above 100. The pulse improved in quality, and the extremities were no longer cold, clammy or cyanotic.

The plasma alpha amino nitrogen had risen to a level of 6.1 mg per 100 cc 5 hours after entry and continued elevated during the next 7 hours. The plasma nonprotein nitrogen concentration, which had been 30 mg on entry, was 40 mg per

culatory collapse, as well as a slight rise in the serum alpha amino nitrogen concentration to 6.2 mg per 100 cc. There were progressive hoarseness and respiratory distress, and the patient died of respiratory failure 16 hours after injury. Autopsy revealed no significant hepatic morphologic changes.

DISCUSSION

The data show that in most patients with extensive deep burns there was a significant elevation of the serum or plasma alpha amino nitrogen concentration in the first twenty-four hours after injury. This was observed in 7 of 8 patients with burns, chiefly deep, involving 35 per cent or more of the body surface. Marked hemoconcentration and clinical shock were present in all but 1 of these pa-

FIGURE 2 Case 5

100 cc at the peak of the alpha amino nitrogen rise and continued to rise to a level of 50 mg per 100 cc. The patient had occasional periods of respiratory distress, which were relieved by intravenous aminophyllin. The temperature was about 103.5°F.

Twenty-four hours after injury the patient suddenly died from respiratory failure. Autopsy revealed no significant hepatic morphologic changes.

CASE 5 F M, a 78-year-old man with a noncontributory history, received flame burns of 35 per cent of the body surface shortly before entry. The burns were mixed dermal and deep. Some damage to the respiratory tract had also been sustained. The data are presented in Figure 2.

Examination on entry revealed an elderly, apathetic man, with cold, clammy, cyanotic extremities. The blood pressure and pulse were not obtainable. The hemoglobin was 129 per cent, the nonprotein nitrogen 35 mg per 100 cc of serum, and the serum alpha amino nitrogen concentration 7.6 mg per 100 cc. Plasma, whole blood and normal saline solution were given intravenously. The hemoglobin varied between 118 and 132 per cent, and the nonprotein nitrogen rose to 50 mg per 100 cc of serum. The serum alpha amino nitrogen fell from the initial level of 7.6 to 5.8 mg per 100 cc 4 hours later. During this period the blood pressure and pulse were satisfactory. Thereafter, there were 2 brief periods of cir-

culation. In some patients, however, the rise in plasma alpha amino nitrogen was observed before the onset of hypotension, and in others the elevation persisted after the blood pressure returned to normal. These findings are similar to those reported by Hoar and Haist⁸ following tourniquet injury to rats. Elevation of the serum alpha amino nitrogen concentration has also been reported from this laboratory⁹ in patients with so-called "medical shock." The correlation of increased alpha amino nitrogen with the severity of shock was marked in these cases.

An increased nonprotein nitrogen concentration in the blood plasma was usually observed in the patients in the present series. In all but 1 case, however, the rise in plasma alpha amino nitrogen concentration occurred at a time when the nonprotein nitrogen concentration was still normal. It has previously been reported from this laboratory¹⁰ and elsewhere¹¹ that protein catabolism proceeds at a very

gh rate in patients with extensive burns. It has generally been accepted¹² that a rise in the over-all nitrogen turnover in the body does not lead to an increase in the plasma alpha amino nitrogen concentration, but when the rate of nitrogen metabolism is markedly increased and the liver is not functioning normally, there is probably some rise in the plasma alpha nitrogen.¹³ Although there is no direct evidence that abnormalities of liver function existed in this series of patients, it is likely that some disturbance was actually present. This is suggested by the elevation of the Quick prothrombin time in most cases. Engel et al¹³ and Wilhelm and his associates¹⁴ have shown in animals that hepatic function is abnormal during hemorrhagic shock, and have specifically demonstrated that the ability of the liver to deaminate amino acids is impaired. Thus, hyperaminoacidemia is probably related to a combination of an increased production of amino acids and a decrease in the rate of deamination by the liver. This view has also been expressed by Engel et al,¹³ Hoar and Haist⁸ and Wilhelm and his associates¹⁴ to account for the rises in plasma alpha amino nitrogen observed in shocked animals.

SUMMARY

Plasma or serum alpha amino nitrogen concentrations were elevated in 8 of 12 patients with thermal burns.

There was a close correlation among the elevation of the plasma alpha amino nitrogen concentration, the extent of the burn, the degree of shock and the prolongation of the Quick prothrombin time.

In some cases the elevation of the alpha amino nitrogen occurred before marked hypotension was present, and persisted after the blood pressure returned to normal.

The rise in plasma alpha amino nitrogen concentration occurred before that in the nonprotein nitrogen concentration.

It is postulated that hyperaminoacidemia is the result of an increased production of amino acids, together with a decrease in the rate of deamination by the liver.

globin was 141 per cent and the alpha amino nitrogen concentration 4.2 mg per 100 cc of plasma.

During the next 5 hours small amounts of water were administered orally, no other fluids being given. The patient gradually went into profound circulatory collapse, no blood pressure or pulse being obtainable for the last half hour of this period. The extremities were cold, clammy and cyanotic. There had been no output of urine. The hemoglobin had risen to 172 per cent whereas the plasma alpha amino nitrogen concentration had risen slightly—to 4.8 mg per 100 cc. Administration of plasma was then begun, and during the next 2 hours the systolic blood pressure was kept between 80 and 90 and was thereafter above 100. The pulse improved in quality, and the extremities were no longer cold, clammy or cyanotic.

The plasma alpha amino nitrogen had risen to a level of 6.1 mg per 100 cc 5 hours after entry and continued elevated during the next 7 hours. The plasma nonprotein nitrogen concentration which had been 50 mg on entry, was 40 mg per

cent, as well as a slight rise in the serum alpha amino nitrogen concentration to 6.2 mg per 100 cc. The patient died of respiratory failure 16 hours after injury. Autopsy revealed no significant hepatic morphologic changes.

DISCUSSION

The data show that in most patients with extensive deep burns there was a significant elevation of the serum or plasma alpha amino nitrogen concentration in the first twenty-four hours after injury. This was observed in 7 of 8 patients with burns, chiefly deep, involving 35 per cent or more of the body surface. Marked hemoconcentration and clinical shock were present in all but 1 of these pa-

FIGURE 2 Case 5

100 cc at the peak of the alpha amino nitrogen rise and continued to rise to a level of 50 mg per 100 cc. The patient had occasional periods of respiratory distress which were relieved by intravenous aminophyllin. The temperature was about 103.5°F.

Twenty-four hours after injury the patient suddenly died from respiratory failure. Autopsy revealed no significant hepatic morphologic changes.

CASE 5 F M, a 78-year-old man with a noncontributory history, received flame burns of 75 per cent of the body surface shortly before entry. The burns were mixed dermal and deep. Some damage to the respiratory tract had also been sustained. The data are presented in Figure 2.

Examination on entry revealed an elderly, apathetic man, with cold, clammy, cyanotic extremities. The blood pressure and pulse were not obtainable. The hemoglobin was 129 per cent, the nonprotein nitrogen 35 mg per 100 cc. of serum, and the serum alpha amino nitrogen concentration 7.6 mg per 100 cc. Plasma, whole blood and normal saline solution were given intravenously. The hemoglobin varied between 118 and 132 per cent, and the nonprotein nitrogen rose to 50 mg per 100 cc. of serum. The serum alpha amino nitrogen fell from the initial level of 7.6 to 5.8 mg per 100 cc 4 hours later. During this period the blood pressure and pulse were satisfactory. Thereafter, there were 2 brief periods of cir-

culatory collapse, as well as a slight rise in the serum alpha amino nitrogen concentration to 6.2 mg per 100 cc. The patient died of respiratory failure 16 hours after injury. Autopsy revealed no significant hepatic morphologic changes.

In some patients, however, the rise in plasma alpha amino nitrogen was observed before the onset of hypotension, and in others the elevation persisted after the blood pressure returned to normal. These findings are similar to those reported by Hoar and Haist⁸ following tourniquet injury to rats. Elevation of the serum alpha amino nitrogen concentration has also been reported from this laboratory⁹ in patients with so-called "medical shock." The correlation of increased alpha amino nitrogen with the severity of shock was marked in these cases.

An increased nonprotein nitrogen concentration in the blood plasma was usually observed in the patients in the present series. In all but 1 case, however, the rise in plasma alpha amino nitrogen concentration occurred at a time when the nonprotein nitrogen concentration was still normal. It has previously been reported from this laboratory,¹⁰ and elsewhere¹¹ that protein catabolism proceeds at a very

important in the dispute over the question whether allergy of dermatophytosis predisposes to the development of contact dermatitis. Both groups included that it did not. These two statements are contrary to our experience in private industrial practice and to the opinion expressed by Neal and Anmons.⁴⁴ Examinations in offices and at plants showed that less than 5 per cent of workers demonstrate clinical evidence of fungous infections. We so believe that the role of cutaneous sensitization is well established. The mere presence of dermatophytids on the hands produces sites of lowered resistance sufficient to break the skin and allow the mechanical and chemical contacts of industry to aggravate the original eruption.

Conant et al.⁴⁵ describe a long list of mycotic infections, of which the following may be classed as attributable to occupational contacts. Actinomycosis is found in agricultural workers and is twice as frequent in men as in women. North American blastomycosis is presumably not contagious but has been acquired by direct contact, the cases reported being those of a physician infected while performing an autopsy and an infant infected from a cutaneous lesion on the arm of a nurse. The sex ratio is 9 males to 1 female, and the disease is found mostly among the poorer classes. Coccidioidomycosis is an infection carried in the soil and by wild rodents, laborers are likelier to develop the severe form than workers in other occupations, and laboratory workers become infected by inhaling spores from dried cultures. A recent study of the primary form of this disease in Army camps showed that 0.2 per cent of the cases developed into a progressive and fatal form. South American blastomycosis also occurs in a ratio of 9 males to 1 female, the disease develops most frequently in manual laborers whose work is of such a nature that vegetative material is brought into contact with the skin. Chromoblastomycosis affects the laboring classes almost exclusively. Moniliasis causes lesions of the hands in housewives, bakers, waiters, bartenders and fruit packers whose hands are macerated by frequent soaking in water. Sporotrichosis is apparently acquired from plants, although it may be contracted from infected animals. The disease occurs oftener in men than in women, especially in farmers, laborers and horticulturists. Maduromycosis is also more frequent in men than in women, in 100 cases cited by Bocarro,⁴⁶ 91 of 92 men were farmers and 7 of 8 women were wives of agriculturists. Aspergillosis is an infection occurring in persons often exposed to massive doses of spores, as in squab feeders who take grain onto their mouths to moisten it, fur cleaners who use rye flour as a grease remover and agricultural workers exposed to dust from threshing machines. Certain species of mucoromycosis produce epidemics of paronychia among orange workers. Rhinosporidiosis has been reported only 13 times in the United States, the disease develops in persons who swim or dive in

stagnant water and is frequent among the sand divers of India.

Insect Infestations

Saunders⁴⁷ reports 2 cases of workers handling straw who developed an itchy eruption. Examination of the straw revealed tyroglyphid mites. The cutaneous manifestations were excoriated urticarial papules, splotchy erythema and intense itching of the neck, face and forearms.

Dermatitis from fowl mites occurring in 2 persons in the same household is reported by Knotts.⁴⁸ *Dermanyssus gallinae* was identified as the cause. The patients' clothing was infested with these mites while they were gathering eggs, tending chickens and cleaning the coops. The bites on the skin became papules with pruritus, which on scratching became excoriated and then crusted. Such patients complain of nocturnal itching, because these mites bite at night. This condition is confused with scabies, but the presence of mites on the clothing, the lack of burrows and the patient's occupation serve to differentiate the two conditions.

In a review of occupational dermatitis,³² so-called "grocer's itch" occurring in handlers of dried fruits is mentioned. Dried dates, figs, prunes, apples and pears are sometimes infested with mites known as *Carpoglyphus passulorum* and *Glyciphagus domesticus*. Tea leaves are sometimes infested with a mite known as *Rhizoglyphus parasiticus*, and wheat may contain a mite known as *Aleurobius farinae*.

CHEMICAL AGENTS

The group of chemical agents causing dermatoses is a large one, comprising the acids, alkalis, salts, hydrocarbons, crude coal-tar products and other organic compounds.

Acids

Schwartz⁴⁹ reports an unusual form of occupational dermatitis that occurred in a plant manufacturing hydrochloric acid. The outbreak occurred after a change was made in the manufacturing process, consisting in the addition of 0.4 per cent of soft coal to the salt briquets from which the acid was made. One of the towers in which hydrochloric acid gas was absorbed by water was cleaned out, and all of 13 men thus engaged developed dermatitis after coming into contact with a yellow, waxy deposit on the fan. Eight months later 27 men who cleaned out another tower also developed dermatitis. The eruption began with itching and burning, and edema of the face and eyelids. After the eruption had subsided, there remained comedones, pustules and acnelike cysts. Patch tests with the waxy substance, which contained 5 per cent hydrochloric acid by weight, were positive. This is a primary irritant.

MEDICAL PROGRESS

OCCUPATIONAL DERMATOSES (Concluded)

J G DOWNING, M D,* AND S J MESSINA, M D †

BOSTON

VITAL AGENCIES

Bacterial Infections

Lebowich, McKillip and Conboy³⁷ report 3 cases of cutaneous anthrax. All the patients were working in leather tanneries, where they handled imported skins. After an average incubation period of one to three days they developed anthrax of the skin, which began as a single, small, red papule on an exposed surface that enlarged rapidly, with development of a central necrotic brownish-black eschar surrounded by a pink, doughy swelling and pink vesicles. No pain was experienced but a sense of fullness and numbness at the site of infection. The constitutional symptoms were persistent headache, fatigue and weakness and also fever.

Ecthyma contagiosum, which is an infection frequent in animals, is reported by Kingery and Dahl³⁸ as occurring in a farm worker who treated sheep for so-called "fluke disease." The animals' mouths were forcibly opened, and in this process the fingers were traumatized. Many of the animals had scabs or pustular lesions on the lips. Three lesions developed on the right thumb, and there were similar ones on the fingers of each hand. The lesions, which were firm papules or papulovesicles on an erythematous base, cleared within a week with mild treatment.

Mycotic Infections

One of us (J G D³⁹) has shown that persistent eruptions on the hands, frequently labeled fungous infections by industrial physicians and inexperienced dermatologists, are usually due to secondary infection by pyogenic organisms. Ayers and Anderson⁴⁰ state that without confirmatory evidence a diagnosis of fungous infection of the hands stands an 88 per cent chance of being wrong. A positive diagnosis can be made only through laboratory evidence.

The hands and feet of 406 patients with a contact dermatitis of more than three months' duration were examined by a trained mycologist working under the supervision of one of us (J G D³⁹), because it is often said that fungus is a secondary invader and prolongs contact dermatitis. Direct microscopic examination of scrapings showed fungous infection on the hands of 5 patients, and cultures showed infection on the hands of 2.

Superficial and deep-seated mycotic infections affect workers. When fungi are regularly found in

an occupational contact, it is reasonable to assume that the worker suffering from organisms peculiar to his labor has an occupational disease. Among workers exposed are those who till the soil or come in contact with plants, hay, straw and animals and their by-products, such as feathers, silk, wool and leather. Kennel keepers acquire microsporosis. Dairymen and herders suffer from trichophytosis due to an ectothrix. Dermal moniliasis occurs in bakers, preserve packers, fruit handlers, salad makers and dishwashers. Deep-seated infections are usually found in farmers, cattlemen, florists, horticulturists, wood handlers and research workers. In Massachusetts primary fungous occupational infections are comparatively rare, but industrial physicians should not only know the fungi to which the worker is exposed but also be trained to prepare and to recognize cultures of fungi.

The most striking report of recent years is that of du Toit⁴¹. In South Africa in 1927 sporotrichosis made its appearance in the gold mines of the Witwatersrand when 14 native workers were found to be suffering from infections due to *Sporotrichum beurmanni*. In 1941, 74 cases were reported in two other mines. All these patients were timber boys. From the middle of 1941 to February, 1942, a total of 650 cases of sporotrichosis was found in an underground shaft where 2500 natives were employed. The epidemic then began to spread among European workers. The company accepted responsibility on the assumption that the disease always followed injury, no matter how insignificant it might be. The clinical types occurring in the mines included the classic lymphangitic type, seen in America, and the multiple ulcerative type, seen in France. The infection was undoubtedly brought into the mine by a native from the tropical east coast. The fungus was isolated from the air and timber in the mines. Treatment, which was simple and effective, consisted of large doses of potassium iodide by mouth, to a total of 200 gm.

Peck and his associates believe that dermatophytosis and its allergic manifestations are not an important factor in lost time among industrial workers.⁴² In the report of the Council on the Treatment and Prophylaxis of Dermatophytosis,⁴³ based on the work of the United States Public Health Service, it is stated that it appears reasonable to assume that more than 50 per cent of persons in industry are affected by dermatophytosis, but it is also affirmed that the evidence of Peck and his associates is most

A drum containing the compound burst, igniting the clothing of a girl employed in unloading drums. The flames were soon extinguished, but the portion of the skin in contact with the sodamide suffered severe burns. The patient died the next day. Autopsy showed acute fibrinotic inflammation of the larynx, trachea and bronchi and many local second-degree burns on the skin.

Methyl Bromide

Butler, Perry and Williams⁵⁶ report a case in which 2 men whose boots were in contact for five hours with methyl bromide, a fire-extinguisher fluid, developed large blisters of the feet. Wyers⁵⁷ calls attention to the symptoms of toxicity of this compound. Brief exposure to the gas caused headaches, smarting of the eyes, cough, loss of appetite, abdominal discomfort and numbness of the feet. Methyl bromide is used in industry as a methylating agent, for refrigeration purposes, as a fumigant and for the control of rodents and fleas. The liquid form rapidly penetrates the clothing, even boots and rubber covering. The characteristic skin lesion is a large blister.

Zinc Chromate

Hall⁷ reports that of 132 persons sensitive to zinc chromate primer, 90 (68 per cent) were sensitive to zinc chromate only. The average duration of exposure before the eruption developed was seven months. Nummular eczematous plaques or groups of papules appeared on the radial and flexor aspects of the wrists, the dorsal aspects of the proximal portions of the thumbs and the volar and ulnar aspects of the forearms.

Lead Arsenate

Monahan⁵⁸ reports an unusual case in which a laborer handling bales of dried pumice in a vinegar factory developed contact dermatitis from the dust, which showed a strongly positive qualitative test for arsenic. It was found that the apples whose peelings were used in the manufacture of vinegar had been sprayed with lead arsenate before being dried.

Vinyl Carbazole

Exposure to vinyl carbazole, according to Tabershaw and Skinner,⁵⁹ resulted in dermatitis in two plants, where the compound was used in manufacturing electric equipment. It is employed in the polymerized form after 98 per cent pure carbazole is treated with acetylene under heat and pressure and filtered, purified and dissolved in monochlorobenzene in the presence of a catalyst. The white amorphous substance is insoluble in water but soluble in chlorinated hydrocarbons, petroleum hydrocarbons and fats.

Tricresyl Phosphate

Gaul and Henneger⁶⁰ report a case of dermatitis bullosum produced in the seborrheic areas of the

body by contact with tricresyl phosphate which was used as a substitute for plasticizer for adhesive tape. The dermatitis was not found in the area of contact, but disappeared on removal of the tricresyl phosphate and recurred when further patch testing was done. The authors stress the significance of a chemical that can invade unbroken skin and produce cutaneous lesions indistinguishable from established disease patterns of seborrhea.

Trichlorethylene Gas

A case of widespread dermatitis due to the inhalation of trichlorethylene gas is reported by Baker and White.⁶¹ There have been no previous reports in the literature of such dermatitis from the inhalation of vapor. A foreman whose office was twenty feet from a degreasing unit suffered diffuse erythematous eruptions of the entire body. The lesions disappeared when he was away from his work but reappeared on his return. When he wore a gas mask no dermatitis occurred, but when he failed to wear it severe burning and pruritic eruptions developed within a few hours. One of us (J G D) had a patient who on exposure to trichlorethylene developed a herpetic eruption of the face and loss of sensation of taste.

Benzidine

Baer⁶² reports a recurrent pruritic eruption on the hands and face of a physician who performed benzidine tests on stool specimens. It recurred each day that he performed the test, the eruption starting on the fingers of the left hand. Patch testing showed benzidine to be the cause, benzidine powder producing an extremely strong eczematous reaction.

Explosives

The explosives causing most cases of dermatitis are tetryl, TNT (trinitrotoluol), fulminate of mercury, ammonium picrate and picric acid, smokeless powder, amatol, amonal, hexite, lead styphnate, sensol and lead azide. Nitroglycerin does not produce dermatitis but can be absorbed through the skin and cause cardiovascular disease.

Tetryl About 4 per cent of tetryl workers develop dermatitis,⁶ but most cases occur in the loading areas. Tetryl manufacture and pellet production are to some extent closed processes, which accounts for the small number of cases of dermatitis. Peck, Gant and Schwartz⁶ report higher percentages of tetryl workers developing dermatitis. Allergic dermatitis is caused oftener by tetryl than by any other explosive.^{19, 63, 64} The eruption appears in newly employed workers within one or two weeks on exposed surfaces — on the face, hands and forearms — and secondarily where dust collects — on the wrists, back of the neck, ankles and feet. The face, hair and hands are stained yellow. Associated symptoms are epistaxis, dryness of the throat and cough.

TNT Sensitization dermatitis is produced by TNT but not so frequently as by tetryl. The derma-

Alkalies

An eczematoid eruption affecting the back of the hands and the flexor surface of the forearms is reported by Whitwell⁵⁰ as arising from the carbonizing of steel. During this process organic carbonizers are mixed with sodium bicarbonate or barium carbonate and the impregnated pellets are packed by hand around the steel. The cause of the dermatitis is the sodium bicarbonate in the pellets, which even after being washed are still strongly alkaline. The barium carbonate is not so harmful. The rash developed after workers had been thus employed for several months. Such workers should do no carbon packing when they are sweating or when their arms are wet after washing, otherwise they soon have a strong solution of soda on their skin.

Dural

Hall⁷ reports 10 cases of dermatitis due to dural, representing 5 per cent of 202 cases of occupational dermatitis in aircraft workers. Dural is an alloy composed of 95 per cent aluminum, 4 per cent copper, 8.5 per cent each of manganese and magnesium and traces of iron and silicon. The eruption consists of scattered pale-pink, fine papules, usually excoriated and covered with sanguinous crusts. The lesions are located on the forearms. In 1 of these cases they were on the flexor surface of the wrists, the sides of the neck were affected in half the cases. The hand and fingers were not involved. Each of the patients showed a slight or moderate reaction to patch tests with dural drillings. The duration of exposure before evidence of sensitization appeared averaged slightly over five months.

Aluminum

In this same series Hall⁷ encountered 4 cases of dermatitis due to aluminum. Each patient showed a slight reaction to aluminum filings. This eruption is evanescent and may disappear within twenty-four hours away from work. The lesions are wheal-like and erythematous, appearing on the forearms, wrists, face and neck. The average duration of exposure is four and a half months.

Selenium Dioxide

Selenium dioxide is used extensively in the electric industry. Workers with pure selenium did not develop skin trouble, but those working with the dioxide compound had typical reactions.⁵¹ A crystal of selenium dioxide under the fingernail produces a painful reaction lasting for about two days. The pain then subsides somewhat, and a small red spot remains. This is followed by a small scar in the area. In severe cases necrosis develops in areas of contact with this compound. There is a burning sensation, intolerable at times. In the series reported, patch tests with pure selenium produced no reaction, but those with selenium dioxide caused such severe reactions that the patches were removed after a few

hours. The reactions were painful, and vesicles developed at the site tested, with eventual deep necrosis. This report proves the danger of patch tests with chemicals that are undoubtedly primary irritants.

Cobalt

Cemented carbides are made from tungsten, tantalum and titanium carbides, carbon and metallic cobalt. In a plant manufacturing these materials, 20 men who had worked in the metal room for a month or more before developing dermatitis were examined.⁵² The eruption was erythematous and papular. Some lesions were ringed, with clear centers, appearing on the cubital spaces, the sides of the neck, the eyelids, the flexor aspects of the forearms and the backs of the hands. In 2 workers who swept the dust from the floor, patches of dermatitis appeared on the external malleolus and ankle. Patch tests on 6 workers showed negative reactions to oxides of tungsten, tantalum and titanium and to carbon but positive reactions to metallic cobalt and to the black powder containing all the metals. Two controls, not working in the plant, gave negative reactions to all metals and thus showed that this is a sensitivity dermatitis. Some of the workers developed tolerance and were able to continue in this work.

Silver

In a case of argyria reported by Wigley and Deville⁵³ the black pigmentation of the skin was due to constant exposure to silver nitrate.

Beryllium

In the last four years, 170 cases of beryllium poisoning have been seen in three plants.⁵⁴ The manifestations included dermatitis, chronic skin ulcers and inflammatory changes in the respiratory tract. The severest manifestation was a diffuse pneumonitis, which caused the death of 5 workers. In the processing of ore, beryllium oxide is extracted under a high temperature from crushed inert ore beryl by acids and fusion methods. Fumes and dust encountered at various steps in this process were the cause of the poisoning. Contact dermatitis and skin ulcers occurred in 42 workers, usually accompanied by rhinitis and nasopharyngitis. The dermatitis occurred within a week after starting work involving contact with beryllium sulfate, beryllium fluoride or beryllium oxyfluoride. The eruption, which was edematous and papulovesicular, occurred on the hands, arms, face and neck, with intense itching. Ulcers were caused by a beryllium crystal deposited in the skin, a small indurated papule resulted and progressed to necrosis. Early excision and curettage of the site afforded complete healing.

Sodamide

A case of acute sodamide poisoning with a fatal result is reported by Pozhariskii and Khodzhash.⁵⁵

with rubber or some other material prevented dermatitis

MISCELLANEOUS CASES

Sterling⁷² reports a severe dermatitis of four years' duration in a waitress. The areas affected were the flexor surfaces of the forearms and the fingertips, the fingers were either split or showed oozing crusted patches. A germicidal powder known as Microlene was found to be responsible, the patient having handled dishes washed in this chemical solution.

Nine cases of contact dermatitis in a morphine factory were reported by Dore, Thomas and Green.⁷³ The average period between the beginning of employment and the appearance of dermatitis was fourteen and a half weeks. The eruption began as an irritating erythematous dermatitis of the eyelids, sometimes with edema. The nape of the neck and the area below the chin were next involved in women, and the collar area in men. The specific sensitizer was not found.

According to Goodman,⁷⁴ cold-wave "permanents" affect the molecular structure of the skin as well as the hair. This is a simple chemical reaction, not an allergic one. Thioglycolic acid should be suspected when one encounters a dermatitis consisting of erythema, vesicles, fissures, pustules, lichenification and itching of the hands of workers dealing with cold-wave fluids. Commenting on an article by Cotter,⁷⁵ however, McCord⁷⁶ makes the following observations: there is no primary skin irritation from thioglycolic acid or alkaline derivatives at levels below 8 per cent and no evidence of sensitization and allergic responses with properly prepared materials under any circumstances, hydrogen sulfide formation can be controlled through stabilization, and no measurable systemic responses occurred in his tests on animals after parenteral introduction.

A baker complaining of a skin eruption of one year's duration was found to be sensitive to benzoic acid in the improved flour he was using.⁷⁷ When he substituted nonimproved flour, the dermatitis, which affected the hands, neck and chest, rapidly disappeared. A patch test with 6 per cent benzoic acid in liquid petrolatum gave a positive reaction.

A month after administering penicillin to hospital patients a physician developed a dermatitis on the skin of the upper extremities and face.⁷⁸ A chemist was observed to have contact dermatitis a year after beginning work with sodium penicillin.⁷⁹ Patch tests with this compound had to be discontinued after twenty-seven hours because of itching and burning. One of the 2 cases of allergic reaction to penicillin reported by Barker⁸⁰ occurred in a medical officer who handled the drug under laboratory conditions for several months. He spilled it on his hand, and itching of the face developed on the following day. Later an acute dermatitis of the face and neck occurred. A patch test with penicillin gave a positive reaction in twelve hours.

DIAGNOSIS

The diagnosis of occupational dermatosis is based on the history, the sites of the eruption and its characteristics. Careful history taking cannot be overstressed. The history should contain information concerning the length of time the worker has been engaged in a particular job, the time and place of the eruption and the characteristics of the original lesion. A history of a similar eruption in a fellow worker may be helpful but is often misleading. A knowledge of the industrial processes involved is invaluable to the physician, but the rapid increase in new processes makes it impossible for any one person to possess such knowledge. The physician should therefore request advice from the employer, the insurer, the safety engineer and the chemist.

Many report forms have been tried by one of us (J G D), but they are for the most part of little value. Peck⁸¹ proposes a new form for reporting industrial dermatitis. It is fairly comprehensive and might be of value in a single plant, but for general use it takes too much for granted.

Occupational dermatoses usually begin on the exposed parts of the body — the hands, fingers and forearms if the offending substance is a solid or a liquid, and the face or neck if a vapor is involved. In dusty occupations, a dermatitis often starts in the flexural areas above the tops of the shoes. Having the patient strip before examination prevents many an embarrassing situation. Since the skin can express itself in only a limited way, dermatitis tends to manifest itself in the lesions previously described, whether or not it is occupational, but some of the eruptions are characteristic of the irritant involved. For example, acne-like lesions of the face are a characteristic eruption of the chlorinated naphthalenes¹⁵, folliculitis, comedones and furunculosis of the hairy parts of the body are seen in cutting oil eruptions¹⁶, paronychias occur in fruit handlers³², a characteristic staining of the skin is caused by explosives, and the helmet type of dermatitis is produced by fumes, vapors and dusts.

DIFFERENTIAL DIAGNOSIS

A sound knowledge of dermatology is a prerequisite for correct diagnosis. Occupational dermatoses must often be distinguished from such diseases as seborrheic dermatitis, fungous infections, lichen planus, impetigo contagiosa, pityriasis rosea, neurodermatitis and contact dermatitis arising from nonoccupational activities. Dermatitis from shoes⁶³ or wearing apparel⁸³ must also be differentiated. Some diseases that are normally not occupational — such as fungous and pyogenic infections, keloids from burns, radiodermatitis, keratoses and even cancer — may arise from occupational exposures. The prime requisite in the diagnosis of occupational dermatoses is a knowledge of the principles of dermatology, so that one may classify the eruption presented. Next in importance is an accumulation of

titis chiefly affects the hands. The cutaneous manifestations are edema, papules and deep-seated vesicles, especially on the palms.¹⁹ Other regions frequently affected include the wrists, forearms, neck creases and feet.⁶⁴ The face is rarely involved. There is considerable staining of the hands.

Fulminate of mercury This explosive, which is more sensitive than tetryl and is used in detonators and primers, causes ulcers of the skin if it enters abrasions and also sensitization dermatitis.¹⁹ The eruption appears first on the backs of the hands and the forearms as erythematous lesions, which tend to remain discrete, and on the face as erythema, with edema of the eyelids and also conjunctivitis.⁶⁴ The irritation develops on the fourth to the sixth day of contact.

Ammonium picrate and picric acid These explosives are used as bursting charges. They cause yellow discoloration of the skin and hair and a sensitization dermatitis of the face.¹⁹

Smokeless powder This powder contains dinitrotoluol or diphenylamine, which produces a sensitization dermatitis.

Synthetic Rubber

When the sources of natural rubber were cut off, there was a tremendous increase in the manufacture of synthetic rubber. This process involves several compounds that cause irritation and sensitization dermatitis among workers. Types of synthetic rubber made in this country are buna S, buna N, butyl rubber and neoprene. Comparatively little dermatitis occurs in the manufacture of synthetic rubber, despite the many irritant chemicals employed.⁶⁵ This is explained by the facts that factories are now equipped with mechanical safety devices and that most of the chemical processes are closed. The various compounds used and their effects are as follows.

Butadiene The vapors of this compound are irritating to the eyes, nasal passages, throat and lungs.⁶⁶

Tertiary butyl catechol This compound is an inhibitor, preventing butadiene and styrene from polymerizing while in storage. It is a skin irritant and causes sensitization dermatitis.¹⁹ ⁶⁵

Styrene This is also a skin irritant and sensitizer.⁶⁵

Phenylbetanaphthylamine This antioxidant is a skin sensitizer.⁶⁵

Hydroquinone This compound is usually added to the latex. It is a cause of sensitization dermatitis.⁶⁵

Aluminum chloride This chemical, which is a catalyst, is a skin irritant.⁶⁵

Bardol This is a coal-tar derivative and is both a primary irritant and a photosensitizer.¹⁹ ⁶⁵

Chlorobutadiene This liquid causes erythema of the skin from splashes, even if immediately washed off with water.⁶⁵

Acrylonitrile This compound is extremely toxic, both from vapor inhalation and from toxic absorption. It may cause dermatitis.⁶⁵

Soapstone This substance is used to cover bales of rubber. If it is coarsely powdered its handlers develop dermatitis, especially during the hot months.⁶⁵

Rubber Goods

Mercaptobenzothiazole This accelerator was found to be the most frequent cause of sensitization dermatitis.⁶⁷

Rubber gloves Three cases are reported of physicians who wore rubber gloves and developed itch and dermatitis.⁶⁸ Neoprene gloves were substituted for ordinary latex and were tolerated.

MILITARY CASES

A temporary sensitivity that was specific for woolen clothing has been reported in members of the Canadian Army who had previously been treated several times for scabies with lotions whose principal ingredient was benzyl benzoate.⁶⁹ Two separate lotions were used, but this compound was the only substance common to both and each lotion produced the same result. Patch testing with wool and cotton showed sensitivity to wool only. In no case was the period between use of the lotion and development of wool sensitivity less than two weeks. In some cases discharge from the military service was necessary. This dermatitis should be distinguished from recurrence of scabies.

Dermatitis from contact with a Navy identification tag has been reported.⁷⁰ After forty-eight hours contact with one of these tags, which are made of chrome steel, a steward's mate developed pruritus, burning, marked erythema and vesicles. There was no history of allergy other than urticaria following the ingestion of grapefruit or lemon. The original contact was with the wrist, but the ankle and neck reacted similarly when brought into contact with the tag. The lesions, which developed after two weeks of contact, lasted for over eighteen months. There were no generalized symptoms of chrome poisoning. Excessive sweating may have resulted in greater solubility of chromates as a factor in this sensitivity. No case of this kind had previously been reported.

Dermatitis from the wearing of Army spectacles has been reported.⁷¹ Six cases were seen within three months at a clinic in Scotland. The frames were made of an alloy of nickel, zinc and copper. Patch tests with pure nickel and with alloy plated with nickel gave positive reactions. Tests showed that under conditions of wear in the presence of perspiration and body heat the dissimilar metals of the alloy can set up an electrolytic action and give rise to an allergic phenomenon. In all cases removal of the spectacles brought rapid clearing of the lesions. All the patients but 2 had pityriasis sicca capitis and perspired freely. Prausnitz-Küstner tests were negative, probably because the subjects did not sweat enough. Covering of the spectacle frames

with rubber or some other material prevented dermatitis

MISCELLANEOUS CASES

Sterling⁷² reports a severe dermatitis of four years' duration in a waitress. The areas affected were the flexor surfaces of the forearms and the fingertips, the fingers were either split or showed oozing crusted patches. A germicidal powder known as Microlene was found to be responsible, the patient having handled dishes washed in this chemical solution.

Nine cases of contact dermatitis in a morphine factory were reported by Dore, Thomas and Green.⁷³ The average period between the beginning of employment and the appearance of dermatitis was fourteen and a half weeks. The eruption began as an irritating erythematous dermatitis of the eyelids, sometimes with edema. The nape of the neck and the area below the chin were next involved in women, and the collar area in men. The specific sensitizer was not found.

According to Goodman,⁷⁴ cold-wave "permanents" affect the molecular structure of the skin as well as the hair. This is a simple chemical reaction, not an allergic one. Thioglycolic acid should be suspected when one encounters a dermatitis consisting of erythema, vesicles, fissures, pustules, lichenification and itching of the hands of workers dealing with cold-wave fluids. Commenting on an article by Cotter,⁷⁵ however, McCord⁷⁶ makes the following observations: there is no primary skin irritation from thioglycolic acid or alkaline derivatives at levels below 8 per cent and no evidence of sensitization and allergic responses with properly prepared materials under any circumstances, hydrogen sulfide formation can be controlled through stabilization, and no measurable systemic responses occurred in his tests on animals after parenteral introduction.

A baker complaining of a skin eruption of one year's duration was found to be sensitive to benzoic acid in the improved flour he was using.⁷⁷ When he substituted nonimproved flour, the dermatitis, which affected the hands, neck and chest, rapidly disappeared. A patch test with 6 per cent benzoic acid in liquid petrolatum gave a positive reaction.

A month after administering penicillin to hospital patients a physician developed a dermatitis on the skin of the upper extremities and face.⁷⁸ A chemist was observed to have contact dermatitis a year after beginning work with sodium penicillin.⁷⁹ Patch tests with this compound had to be discontinued after twenty-seven hours because of itching and burning. One of the 2 cases of allergic reaction to penicillin reported by Barker⁸⁰ occurred in a medical officer who handled the drug under laboratory conditions for several months. He spilled it on his hand, and itching of the face developed on the following day. Later an acute dermatitis of the face and neck occurred. A patch test with penicillin gave a positive reaction in twelve hours.

DIAGNOSIS

The diagnosis of occupational dermatosis is based on the history, the sites of the eruption and its characteristics. Careful history taking cannot be overstressed. The history should contain information concerning the length of time the worker has been engaged in a particular job, the time and place of the eruption and the characteristics of the original lesion. A history of a similar eruption in a fellow worker may be helpful but is often misleading. A knowledge of the industrial processes involved is invaluable to the physician, but the rapid increase in new processes makes it impossible for any one person to possess such knowledge. The physician should therefore request advice from the employer, the insurer, the safety engineer and the chemist.

Many report forms have been tried by one of us (J G D), but they are for the most part of little value. Peck⁸¹ proposes a new form for reporting industrial dermatitis. It is fairly comprehensive and might be of value in a single plant, but for general use it takes too much for granted.

Occupational dermatoses usually begin on the exposed parts of the body — the hands, fingers and forearms if the offending substance is a solid or a liquid, and the face or neck if a vapor is involved. In dusty occupations, a dermatitis often starts in the flexural areas above the tops of the shoes. Having the patient strip before examination prevents many an embarrassing situation. Since the skin can express itself in only a limited way, dermatitis tends to manifest itself in the lesions previously described, whether or not it is occupational, but some of the eruptions are characteristic of the irritant involved. For example, acnelike lesions of the face are a characteristic eruption of the chlorinated naphthalenes¹⁵, folliculitis, comedones and furunculosis of the hairy parts of the body are seen in cutting oil eruptions¹⁶, paronychias occur in fruit handlers³², a characteristic staining of the skin is caused by explosives, and the helmet type of dermatitis is produced by fumes, vapors and dusts.

DIFFERENTIAL DIAGNOSIS

A sound knowledge of dermatology is a prerequisite for correct diagnosis. Occupational dermatoses must often be distinguished from such diseases as seborrheic dermatitis, fungous infections, lichen planus, impetigo contagiosa, pityriasis rosea, neurodermatitis and contact dermatitis arising from nonoccupational activities. Dermatitis from shoes⁵² or wearing apparel⁵³ must also be differentiated. Some diseases that are normally not occupational — such as fungous and pyogenic infections, keloids from burns, radiodermatitis, keratoses and even cancer — may arise from occupational exposures. The prime requisite in the diagnosis of occupational dermatoses is a knowledge of the principles of dermatology, so that one may classify the eruption presented. Next in importance is an accumulation of

facts regarding the industrial exposure, and last comes a good measure of common sense. If a worker's hands are wet during the greater part of his working hours, if he is constantly exposed to irritation from fumes and dusts, if an epidemic of eruptions appears in a group of workers, if the skin is splashed with a primary irritant, and if the clothes are soiled for hours with a volatile solvent such as gasoline, it requires no great learning to assume that the worker is suffering from an occupational dermatitis. Careful history taking limits the possible factors, and proper application of a few patch tests solves the problem when the history of the irritating factor is not too evident.

THE PATCH TEST

Patch testing consists in putting a portion of the material to be tested on the subject's skin and covering it first with linen and next with a larger piece of adhesive or other impervious material. Although the actual technic is simple, knowledge of when to perform the test, with what materials and in what dilution presents a problem for the expert. Serious consequences can follow the test. Primary irritants should not be used, since some of them are also sensitizers. The latter, in the proper dilution, can be tested. Textbooks usually give tables for guidance. As a rule, products made for wear can be tested full strength or as they are.

It must be realized that because patch testing cannot simulate all the actual conditions of exposure — sweating, friction and other factors to which a worker is subjected — its value is limited. It is an aid in the diagnosis of occupational dermatosis. A recent questionnaire on patch tests⁸⁴ supports the view that although these tests have their limitations, they are of definite value. During a twelve-month period, for example, Howell⁸⁴ was able to prove the exact cause of 250 cases of contact dermatitis by patch-testing with the suspected materials.

Patch-test reactions are recorded as follows: a + reaction shows definite erythema, a ++ reaction shows erythema and papules, a +++ reaction consists of vesiculation, and a ++++ reaction shows a denuded area at the site of contact. A preplacement patch test on the skin is carried out with materials or chemicals that a worker comes in contact with on his job. The advantages of this test enumerated by Keil⁸⁵ consist in eliminating cases of latent hypersensitiveness, placing a person in the right industry and determining whether a substitute chemical should be used. The following objections have been raised to this type of testing: a person may be sensitized to the material tested, he may sue, he may have a positive reaction and yet show no clinical evidence of dermatitis, and evidence of sensitization is not always a sure indication that the worker will suffer a dermatitis. It has been proved that many workers, such as bakers who have never had a cutaneous eruption, react to patch tests

with substances to which they are exposed. Again, many workers handle sensitizers for twenty years or more before suffering from a cutaneous disturbance. In still other cases those who continue their work and subsequently become immune or less susceptible are shown by patch tests to be still sensitized, but are able to maintain tolerance to their exposures.

So-called "prophetic patch testing" is done with the purpose of foretelling whether a substance will or will not produce a dermatitis.⁸⁶ The test is made on 200 or more persons in the usual way. Since the chemicals to be tested are new ones, it is assumed that there has been no contact with them. Two series of patch tests are carried on in the same subjects ten to fourteen days apart. The first series give reactions to primary irritants or produce them in persons previously sensitized, and the second show how many subjects have been sensitized by the first series.

LEGAL ASPECTS

In Massachusetts an occupational dermatosis may be defined in the words used by one of the courts in describing personal injury as "any injury, damage, harm or disease of the skin which arises out of or in the course of employment." Such an injury is compensable if it causes incapacity and takes away a worker's ability to earn wages.

No one is better qualified to decide the diagnosis, the differential data and the etiologic factor than the dermatologist. When specialists disagree, an impartial and duly qualified dermatologist is appointed to examine and report, and his report is considered admissible as evidence, provided that the employee and the insurer have been seasonably furnished with copies of it (General Laws of Massachusetts, Chapter 152, Section 9). The employee who is unable to employ a dermatologist always has the right to an impartial examination.⁸⁶

On October 14, 1935, the Massachusetts Legislature adopted an amendment to permit a claim of industrial disease to be referred to three impartial physicians, who are allowed to examine the patient, investigate working conditions as they deem necessary, and report to the Industrial Accident Board their diagnosis and opinion regarding the cause and extent of incapacity, if any. The report must be made by a majority vote of the referees. The diagnosis should be positive — that is, it should specify the disease or condition found or state specifically that no disease was found. This report is binding and final, but the Board can base its decision on the previous history or on subsequent facts. The diagnosis of the medical referees must be made from the physical signs present at the time of examination, although this diagnosis may be made months after the onset, perhaps when the patient has recovered. As a result, interesting complications have developed. The constitutionality of this statute has been extensively debated. There is no doubt

at it has prevented an employee from having a complete or full trial on his claim of industrial disease when the Industrial Accident Board appoints the three physicians. On the other hand, he is saved the expense of employing one or more experts to testify in a questionable case.³

In April, 1946, the provisions of the Workmen's Compensation Act that provide for the appointment of three medical referees who hold *ex parte* investigations and make reports binding on the Industrial Accident Board were declared unconstitutional by the full bench of the Massachusetts Supreme Judicial Court. The decision, written by Justice James J. Ronan, declared that the 1935 law, amended in 1938, "deprives a party of his fundamental rights" under both state and federal constitutions.

The question of cancer of the skin arising from a single injury is a cause of frequent legal and medical disputes. Such claims as the following are constantly appearing. A thirty-four-year-old man was struck by a splinter from an emery wheel, which penetrated his cheek. Probing for the splinter led to considerable trauma, followed by swelling and suppuration. The swelling became larger and harder. Two months later it measured 1.5 by 2.0 cm and appeared as a sharply defined lesion with a verrucous center, with no pain. Removal and histologic examination revealed a prickle-cell carcinoma.⁴⁷

Perhaps owing to the employment of older workers during the manpower shortage, one of us (J. G. D.) has seen a large increase in the number of workers making claims for skin cancer arising from a single injury or an industrial exposure. Many of these claims present evidence of a slight blow that has received first-aid treatment. Most blows have been on the face, the frequent site of cutaneous cancer in old age. Careful examination and the history of the original injury would have shown that a cancer was already there and that the trauma had caused bleeding at a site where an intact skin would have shown no evidence of injury. This sequence of injury, continued treatment and final recognition of a cancerous growth, together with inept or biased medical testimony, presents facts that few industrial commissioners have the temerity to dismiss.

Whether or not a fatal or disabling cancer was caused by an industrial accident is certainly a question not of law but of fact. If reasonable evidence has been introduced in the proceedings before an industrial board to sustain a finding that an industrial injury, single or multiple, has caused a cancer that resulted in disability or death and the Board so decides, an appellate court in any state in which the general rule laid down above is in force cannot set aside the award or remand the case for further proceedings, even though the court believes that the weight of all the evidence did not justify the decision. In any event, so long as the cause or

causes of cancer are not known, so long as there is an opinion among the medical profession at large to the effect that a single trauma may cause cancer, and so long as physicians are willing to testify under oath that in their professional opinion the disability can and did occur in the case under consideration, the industrial commission cannot be blamed if it sometimes accepts such evidence and grants awards accordingly. In forming his opinion in a given case, the physician should bear in mind the lack of definite knowledge regarding the relation of a single injury to the causation of cancer.

Whether human cancer can be caused by a single accidental injury remains an open question, the results of clinical observations are not conclusive. Although authentic cases are recorded in which cancer arose at the site of injury, the possibility that it was under way before the injury or developed independently of it cannot be excluded. That cancer can and does arise independently of injury and that single injuries become associated with cancer in one way or another in extremely few cases cannot be denied. So far as is known, cancer in animals has not been produced experimentally by a single mechanical injury.⁴⁸ Stewart⁴⁹ states "As far as I know, I have never seen a cancer which I could logically and irrevocably assign to single trauma and, even more important than that, I do not know that anyone has observed the development of a process which could be called 'precancerous' after a trauma."

TREATMENT

There is nothing new to be said about treatment, but it is necessary to reiterate that the use of antibiotics, such as penicillin, or of new bactericidal or fungicidal chemicals has no place in the treatment of uncomplicated industrial dermatoses. Despite the fact that some workers become immune to their contacts, there is no question that when a worker suffers an occupational dermatitis, the sooner he is removed from his work the speedier his recovery will be. The physician should use only soothing remedies, such as wet dressings, lotions and bland ointments.⁵⁰ A valuable new contribution, however, is the use of BAL (British anti-lewisite) in the treatment of cases of chronic arsenical and mercurial poisoning, certain physicians have also been trying it on other industrial cases.⁵¹

NEW HAMPSHIRE MEDICAL SOCIETY

PROCEEDINGS OF THE ONE HUNDRED AND FIFTY-FIFTH
ANNIVERSARY

House of Delegates, May 13 and 14, 1946 (Concluded)

Dr Sycamore then assumed the chair, while Smith presented his report as delegate to the House of Delegates of the American Medical Association

The 1945 session of the American Medical Association was curtailed to a meeting of the House of Delegates, which was held in Chicago on December 3, 4 and 5. Your delegate served on the Reference Committee on Reports of Officers. To expedite the work of the Association and express its policies more promptly, it was voted to hold two meetings of the House of Delegates each year. It was decided that the next session would be held in July, 1946, in San Francisco, and plans were developed for the centennial meeting at Atlantic City in 1947. You are all urged to attend this momentous meeting.

Dr George R. Minot, of Boston, was awarded the Distinguished Service Award, and Dr Harrison H. Shoulders, of Nashville, Tennessee, was elected president-elect. The Section on General Practice of Medicine was established. Dr Roger I. Lee delivered two excellent addresses, which have been published in the *Journal of the American Medical Association*, emphasizing the democracy of the House of Delegates. County medical societies through the state societies and their delegates bring items of business and express their opinions at the meetings. Perhaps our society has been lax in this respect, for your delegate has been instructed only once during the years that he has served.

The sudden end of hostilities and the rapid demobilization of medical officers created such a demand for even the increased number of residencies that, unfortunately, some physicians were unable to obtain them. The same conditions, together with the continuation of the accelerated program in the medical schools, prevented the inauguration of as complete a plan of postgraduate instruction as had been anticipated. You are referred to the *Journal of the American Medical Association* of December 22, 1945, for the details of the excellent work of the Committee on Postwar Medical Service.

President Kretschmer delivered a practical address in which he emphasized the importance of the county medical societies. Since most of the secretaries of the county societies are present, the changes that he proposed will be stated briefly. Scientific meetings of a group of counties, lasting all day and evening and thus ensuring a large gathering, better speakers and a better program, regular meetings devoted to a discussion of ethics, economics and organization, and meetings at which timely educational topics could be presented to a lay audience, and also meetings in association with the social service, relief, political, public health and similar groups.

Major General Paul R. Hawley, acting surgeon general of the Veterans Administration, told about the reorganization of his department so as to attract young physicians, to utilize part-time men in the hospitals, and to provide for the free choice of a physician by a veteran when he needs outpatient care for service-connected disabilities.

The House disapproved the Maternal and Child Welfare Act of 1945, which extends and greatly expands the E M I C program and defines a child as anyone under the age of twenty-one.

It was decided to make permanent the Bureau of Information and to urge each state society to establish a similar information service.

This state information service should collect from various public and private agencies data relating to medical facilities, medical personnel or medical needs

and other information concerning medical care within the state. This information service should at all times be in a position to furnish information concerning areas in need of physicians and a complete picture of the medical facilities, physical and economic aspects of any community within the state.

Your delegate, having done much of this work during the last five years, knows that there is a definite need in New Hampshire for such a service.

The Committee on National Emergency Medical Service was established, and has suggested that each state society appoint a similar committee. The committee will study the many communications that have been received and the suggestions made by physicians in the armed forces, and will also formulate policies for recommendations to be forwarded through the Surgeon General to the Secretary of War and the Secretary of the Navy expressing the views of the medical profession in planning for proper utilization of the services of physicians in any national emergency. Your delegate recommends the establishment of a similar committee of three civilian physicians who have served with the armed forces.

The Council on Medical Service and Public Relations and its Washington office have done a great amount of excellent work. The Board of Trustees and this Council were instructed to proceed as promptly as possible with the development of a specific national health program, with emphasis on the nationwide organization of locally administered prepayment medical plans sponsored by medical societies. In accordance with these instructions the following steps have been taken: establishment of standards of acceptance for medical-care plans that have the approval of the Council on Medical Service of the American Medical Association, organization of Associated Medical-Care Plans, Incorporated, to establish co-ordination and reciprocity among all these plans, to undertake research, to provide consultation and information services and to engage in a great campaign of public education, establishment of a division of prepayment medical-care plans to administer the activities related to the promotion and development of medical-care plans in all the states, and restatement of the national-health program of the American Medical Association.

There was considerable discussion of President Truman's national-health program and the Wagner-Murray-Dingell Bill. Official disapproval of Section 4 of the bill, which provides for compulsory health insurance, was expressed for the following reasons:

- 1 The Wagner-Murray-Dingell Bill is founded on the false assumption that solution of the medical care problem for the American people is the panacea for all the troubles of the needy.

- 2 This is the first step in a plan for general socialization not only of the medical profession but of all professions, industry, business and labor.

- 3 Positive proof exists from experience in other countries that inferior medical service results from compulsory health insurance.

- 4 A program such as outlined is enormously expensive. It will result in greatly increased taxes for the entire population of the United States.

- 5 Voluntary prepayment medical plans now in operation in many parts of the United States and which are rapidly increasing in number will accomplish all the objects of this bill with far less expense to the people and under these plans the public will receive the highest type of medical care.

NEW HAMPSHIRE MEDICAL SOCIETY

PROCEEDINGS OF THE ONE HUNDRED AND FIFTY-FIFTH ANNIVERSARY

House of Delegates, May 13 and 14, 1946 (Concluded)

Dr Sycamore then assumed the chair, while Smith presented his report as delegate to House of Delegates of the American Medical Association

The 1945 session of the American Medical Association was curtailed to a meeting of the House of Delegates, which was held in Chicago on December 3, 4 and 5. Your delegate served on the Reference Committee on Reports of Officers. To expedite the work of the Association and express its policies more promptly, it was voted to hold two meetings of the House of Delegates each year. It was decided that the next session would be held in July, 1946, in San Francisco, and plans were developed for the centennial meeting at Atlantic City in 1947. You are all urged to attend this momentous meeting.

Dr George R. Minot, of Boston, was awarded the Distinguished Service Award, and Dr Harrison H. Shoulders, of Nashville, Tennessee, was elected president-elect. The Section on General Practice of Medicine was established. Dr Roger I. Lee delivered two excellent addresses, which have been published in the *Journal of the American Medical Association*, emphasizing the democracy of the House of Delegates. County medical societies through the state societies and their delegates bring items of business and express their opinions at the meetings. Perhaps our society has been lax in this respect, for your delegate has been instructed only once during the years that he has served.

The sudden end of hostilities and the rapid demobilization of medical officers created such a demand for even the increased number of residencies that, unfortunately, some physicians were unable to obtain them. The same conditions, together with the continuation of the accelerated program in the medical schools, prevented the inauguration of as complete a plan of postgraduate instruction as had been anticipated. You are referred to the *Journal of the American Medical Association* of December 22, 1945, for the details of the excellent work of the Committee on Postwar Medical Service.

President Kretschmer delivered a practical address in which he emphasized the importance of the county medical societies. Since most of the secretaries of the county societies are present, the changes that he proposed will be stated briefly. Scientific meetings of a group of counties lasting all day and evening and thus ensuring a large gathering, better speakers and a better program, regular meetings devoted to a discussion of ethics, economics and organization, and meetings at which timely educational topics could be presented to a lay audience, and also meetings in association with the social service, relief, political, public health and similar groups.

Major General Paul R. Hawley, acting surgeon general of the Veterans Administration, told about the reorganization of his department so as to attract young physicians, to utilize part-time men in the hospitals, and to provide for the free choice of a physician by a veteran when he needs outpatient care for service-connected disabilities.

The House disapproved the Maternal and Child Welfare Act of 1945, which extends and greatly expands the E. M. I. C. program and defines a child as anyone under the age of twenty-one.

It was decided to make permanent the Bureau of Information and to urge each state society to establish a similar information service.

This state information service should collect from various public and private agencies data relating to medical facilities, medical personnel or medical needs

and other information concerning medical care within the state. This information service should at all times be in a position to furnish information concerning areas in need of physicians and a complete picture of the medical facilities, physical and economic aspects of any community within the state.

Your delegate, having done much of this work during the last five years, knows that there is a definite need in New Hampshire for such a service.

The Committee on National Emergency Medical Service was established, and has suggested that each state society appoint a similar committee. The committee will study the many communications that have been received and the suggestions made by physicians in the armed forces, and will also formulate policies for recommendations to be forwarded through the Surgeon General to the Secretary of War and the Secretary of the Navy expressing the views of the medical profession in planning for proper utilization of the services of physicians in any national emergency. Your delegate recommends the establishment of a similar committee of three civilian physicians who have served with the armed forces.

The Council on Medical Service and Public Relations and its Washington office have done a great amount of excellent work. The Board of Trustees and this Council were instructed to proceed as promptly as possible with the development of a specific national health program, with emphasis on the nationwide organization of locally administered prepayment medical plans sponsored by medical societies. In accordance with these instructions the following steps have been taken: establishment of standards of acceptance for medical-care plans that have the approval of the Council on Medical Service of the American Medical Association, organization of Associated Medical-Care Plans, Incorporated, to establish co-ordination and reciprocity among all these plans, to undertake research, to provide consultation and information services and to engage in a great campaign of public education, establishment of a division of prepayment medical-care plans to administer the activities related to the promotion and development of medical-care plans in all the states, and restatement of the national-health program of the American Medical Association.

There was considerable discussion of President Truman's national-health program and the Wagner-Murray-Dingell Bill. Official disapproval of Section 4 of the bill, which provides for compulsory health insurance, was expressed for the following reasons:

- 1 The Wagner-Murray-Dingell Bill is founded on the false assumption that solution of the medical care problem for the American people is the panacea for all the troubles of the needy.

- 2 This is the first step in a plan for general socialization not only of the medical profession but of all professions, industry, business and labor.

- 3 Positive proof exists from experience in other countries that inferior medical service results from compulsory health insurance.

- 4 A program such as outlined is enormously expensive. It will result in greatly increased taxes for the entire population of the United States.

- 5 Voluntary prepayment medical plans now in operation in many parts of the United States and which are rapidly increasing in number will accomplish all the objects of this bill with far less expense to the people and under these plans the public will receive the highest type of medical care.

The chairman was active in formulating requests for the return to civilian practice of physicians who were badly needed in their respective communities. He is pleased to report that a large number of physicians have considered coming to New Hampshire to practice, and many have already done so. He has answered at least fifty letters of inquiry and interviewed over thirty-five doctors. Although there are still several opportunities in the State for physicians, the areas in the greatest need are now supplied with medical care.

DEERING G. SMITH, *Chairman*
HAROLD I. L. LOVERUD
ANTHONY E. PETERS

Dr. Lewin, for the Committee on Officers' Reports, moved that the Committee on Medical Preparedness be discontinued, and that the by-laws be so changed. This motion was duly seconded.

A member inquired whether all men in the service had returned to civilian life.

Dr. Smith replied that two or three doctors who had been practicing in New Hampshire before the war were still in the service.

The motion was carried.

Dr. Smith then assumed the chair.

Dr. John P. Bowler then presented the following report:

Report of the Committee on Medical Education and Hospitals

During the last year, as in previous war years, there has been a general suspension in the activities of postgraduate training, particularly along the lines of the Commonwealth Fund, which has not resumed its subsidization of postgraduate fellowships.

The New England Postgraduate Assembly will renew its program this fall. This had been successfully operating as a two-day meeting at Cambridge for several years previous to 1942, and committees are now active in preparation for the re-establishment of what was on its way to being an obviously successful venture.

The Speaker's Bureau as operated by this committee principally for the supply of Society members for county meeting programs has continued, but in lesser demand than previously. Until now, when returning men will have made the medical personnel of the State more stable, no circularizing of the membership has been done for the enrollment of volunteers as speakers. Soon this will be undertaken, and a new list accumulated.

Senate Bill 191, which provides for a survey of hospital and health facilities within the various states to provide data for later consideration of federal grants toward the costs of construction of such facilities as needed, has led to the appointment of the New Hampshire State Commission for Hospital Study. This body, which was appointed by the Governor last summer, consists of fifteen members, with Mr. James M. Langley, of Concord as chairman. The medical representation on this commission includes Drs. George C. Wilkins and Jules Gagnon, of Manchester, Dr. Philip McQuesten, of Nashua, Dr. John P. Bowler, of Hanover, and the secretary of the Board of Health. The Governor and Council appropriated \$3000 for the purposes of this commission in the carrying out of its studies.

The State Department of Health has co-operated with the commission in preparing the health-center portion of the study. The State Planning and Development Commission has provided the office quarters, and its director has served as secretary to the commission, directing the work of the field representative, Mary T. Swoboda.

JOHN P. BOWLER, *Chairman*
JAMES W. JAMESON
SAMUEL M. BROOKS

Dr. Lewin, for the Committee on Officers' Reports, recommended that the delegates from the different county societies remind their secretaries that speakers for their various county meetings are available through Dr. Bowler's committee, and moved the acceptance of this portion of the report. This motion was duly seconded and was carried.

Dr. Lewin, for the Committee on Officers' Reports, then moved that the report of the Committee on Medical Education and Hospitals be accepted. This motion was duly seconded and was carried.

Dr. John B. McKenna then presented the following report:

Report of the Committee on Mental and Social Hygiene

I must plead guilty to procrastination in the matter of the report of the committee. Undoubtedly you are aware of the fact that Dr. Baker was to have made this report, but because of his retirement and emigration from New Hampshire, he suggested to Dr. Smith that one of the other members of the committee present the report. The third member of the committee, Dr. Simon Stone, had only recently returned to Manchester, and Dr. Smith therefore asked me some time ago to do this.

To begin with I cannot do much better than forward Dr. Baker's letter to Dr. Smith, in which there are incorporated several valuable suggestions with which I am in essential agreement. My difficulty in making such a report derives from the fact that, being peripherally located, I am not in sufficient contact with the more central problems. Therefore, my remarks can be the result only of essential experiences in connection with the more peripheral problems of psychiatry and mental hygiene in the State.

My first thought in this connection is that the field of psychiatry and mental hygiene in New Hampshire is peculiarly lacking in any effective co-ordination, because there is no one person in a position to do this co-ordination, such as the Commissioner of Mental Diseases in other states. Such a person and his assistants could more directly co-ordinate any efforts toward better psychiatric care and mental hygiene. I believe that under such a person Dr. Baker's suggestion regarding the formation of a state committee on mental hygiene could operate effectively in accordance with Dr. Baker's other suggestions. To these I add the desirability and practical necessity for more widespread use of psychiatric social-service workers, who might bring into contact many otherwise neglected cases of psychiatric problems with psychiatrists and mental hygienists. It has been my experience from practically ten years of psychiatry in the northern parts of New Hampshire, that there are many cases in which earlier psychiatric intervention might have forestalled more serious consequences. This would also imply the desirability of more peripherally located mental hygiene clinics, such as those existing in other parts of the State. Such additional clinics might well be located in places like Hanover and Littleton. Again, I have no basis for any knowledge of conditions in the more eastern parts of the state.

Some time ago, in a conversation with Dr. Dolloff, I brought up for discussion the possibility that the State could employ one or more psychiatric social-service workers whose duty would be to make periodic trips through the rural parts of the State to investigate and call to the attention of psychiatrists any specific needs for psychiatric help.

There is also an undoubted need for more widespread public education in psychiatric matters. In this connection it is worthy of note that the American Psychiatric Association has formed a committee on reorganization among whose proposed plans are included definite attention to organized programs for such education throughout the country. It might be well to look into this matter so far as New Hampshire is concerned, and I shall have definite information on this point after my attendance at the American Psychiatric Conference in Chicago later this

Dr Lewin, for the Committee on Officers' Reports, recommended that the House of Delegates establish a new standing committee, the New Hampshire Emergency Committee, consisting of three doctors formerly of the armed forces. This motion was duly seconded.

Dr Dye stated that if this were to be a standing committee the by-laws would have to be amended. The Secretary asked what the committee was to do. Dr Smith answered that the committee would try to find out what was wrong with the medical organization in the last war and prepare for the next war. A great many complaints and a great many criticisms, some constructive, had been received from medical officers and others who had served in the war. A number of the complaints had been turned over to this Committee of the American Medical Association, and it had accordingly been recommended that each state find other constructive items of criticism that could be used in the future.

Dr Dye suggested that the Committee on Officers' Reports, together with Dr Smith, draw up an amendment to be submitted for approval on the following day, in such a form that the name and duties of the committee would be specified in the by-laws.

Dr Smith stated the work of the committee could probably be accomplished in a year. It was to be like the Procurement and Assignment Service. All the criticisms that have arisen because of the participation of doctors in the war could be brought out, and constructive criticisms could be offered to the central committee of the American Medical Association, which, in turn, could be forwarded to the Secretary of War and the Secretary of the Navy, who were looking for criticisms.

The Secretary asked whether the Committee on Medical Preparedness could function in such a way. Dr Smith replied that the committee was to be composed of veterans.

The Secretary then inquired if a special committee for one year could take care of the situation. Dr Smith answered that it could.

Dr Lewin asked if the American Medical Association intended to have a national committee that would be permanent. Dr Smith did not believe so.

Dr Lewin, for the Committee on Officers' Reports, then moved that the House of Delegates create a committee, the New Hampshire Emergency Medical Service Committee, consisting of three doctors formerly of the armed forces during the war, to be elected by the House of Delegates for a period of one year or until the next annual meeting of the House of Delegates.

Dr Forsberg suggested that the motion be amended so that the committee would consist of five doctors. Dr Lewin accepted the amendment. This motion was duly seconded and was carried.

Dr Lewin stated the Committee on Officers' Reports had come to no conclusion on the question of

establishment of a bureau of information, but requested open discussion by the delegates.

The Speaker said that during the last year, he had received at least fifty letters and had interviewed over thirty-five physicians regarding moving to New Hampshire. Some of these men had visited New Hampshire. They wanted to know the best locations and what industries were to be found. He said that they were looking for residencies in all types of towns, in the various specialties. He had received letters addressed to the State Planning Commission, the State Board of Health, Dr Metcalf and Dartmouth College Medical School, all of which had been forwarded to him for reply. He believed that in the near future there would be many such requests, especially from men who had gone into the service directly from medical school. The whole effort had been to place these men in towns where no returning physician would be deprived of his practice, and also to attract them to the smaller towns and smaller areas, where there were no doctors. It had sometimes been difficult to interest these men in going to such areas. Dr Smith believed that a central clearing house should be set up, and suggested that the Secretary continue the work in the future, although he was already overworked.

The Secretary replied that he did not come in contact with the units mentioned, and that he did not know the towns very well. He stated that Dr Smith had been a godsend because he knew the situation at present. His only other suggestion was the State Board of Health, which received many requests for information.

The President called attention to the fact that the House of Delegates during the preceding year had created tentatively a committee for this particular purpose, with representatives from each county society. The men were to have been appointed by the county societies themselves, with a central chairman, and there would have been communication between the central chairman and the county-society members, each chosen for his temperament and his willingness and ability to serve as a local information agency from each county.

Dr Lewin, for the Committee on Officers' Reports, recommended that the Society co-operate to the fullest extent with any private prepayment plan of medical care, as a means of warding off a compulsory health program, and moved the adoption of this portion of the report. This motion was duly seconded and was carried.

Dr Lewin, for the Committee on Officers' Reports, then moved that the report of the delegate to the American Medical Association be accepted. This motion was duly seconded and was carried.

Dr Smith then read the following report

Report of the Committee on Medical Preparedness

The cessation of hostilities terminated the necessity of this committee during the past year, and it is recommended that it be discontinued.

the Committee on OPA Assistance be continued until the Government discontinues OPA through gressional action. This motion was duly seconded and was carried.

he report of the Committee on Public Health presented by the chairman, Dr Harris E Powers

The Committee on Public Health started out the year with the following members: Dr Harris E Powers, chairman, Dr Alfred Frechette, and Dr Anthony E Peters. During the course of the year, however, we had the misfortune of losing Dr Frechette, who accepted a call out of the State. New Hampshire and the New Hampshire Medical Society lost a very valuable man through this transfer.

In the previous year your committee had the pleasure of inspecting some of the lumber camps in the northern sections of the State, and this year conducted an inspection tour of the Portsmouth area, which has been one of the more concentrated industrial areas owing to the vast expanse in the Navy Yard during the war. On July 25, 1945, Dr Frechette, Dr McCloud, of the State Health Department, and your chairman proceeded to Portsmouth where we met Dr Peters. An inspection was conducted of one of the large milk plants in Portsmouth, and the method of handling milk from its entry into the plant, the processing of the milk and finally the bottling and preparation for delivery were covered. The pasteurizing of milk and the by-products, such as cottage cheese and ice cream, were followed through by your committee. The progress in the handling of milk in the past twenty years has been remarkable, but there is still room for improvement through the education of employees along sanitary lines. These efforts are being conscientiously carried out by the state health authorities.

From Portsmouth we followed along the South Shore to Seabrook, where the clam industry flourishes. Few people in the State realize the magnitude of this industry, and the small town of Seabrook seems to be the center of this activity. Scattered over the town are small shacks, which are used by the shuckers who receive the clams as they are dug and remove the meat from the shell. These individual industries are all small and few of them have anything like modern equipment. Of the many shacks that we inspected only one had stainless-steel benches, all the rest had wooden trays or benches. The process of shucking consists of removing the clams from the shells—this is all done by hand and with the aid of a short chisel-like knife, each clam is handled separately, the shell being cast in one pile and the clams being tossed in a container of one-gallon content. It was amazing to find that many of the clams had been dug from remote sections in Massachusetts and Maine, shipped to Seabrook in large barrels, shucked, and then transported back to wholesalers throughout New England. This is probably accounted for by the fact that the shuckers have established themselves in this community over a period of many years. They are a more or less isolated group, intermarrying generation after generation. The income of these employees seems adequate, and several of the workers said that they averaged six or seven dollars a day at their work. Their houses are extremely primitive, if the average laborer's house is used as a standard, and their customs and habits are equally singular. If their houses may be used as a guide they seem to have little interest in the niceties of life. The largest plant that we inspected employed ten to twelve people, the average being about six to ten employees. The State Health Department inspects these plants regularly for sanitary conditions and endeavors to improve the standards of the industry by screens on the windows, cleanliness in the shuckers themselves and boiling water and steam for sterilization purposes.

After inspecting the Seabrook area we proceeded to the Hampton Beach area. Some of the fire hazards were inspected and suggestions made, the proximity of the buildings at Hampton Beach result in a great fire hazard, and it is hoped that sufficient equipment will be retained at the beach to prevent such a catastrophe.

There is a great need in the communities that we inspected for education of both employers and employees along sanitary lines, particularly regarding handling of food supplies. It is certainly impossible for the Health Department to cover these territories as frequently as seems necessary with the small staff of inspectors available. It is one thing to make a suggestion and quite another to follow this suggestion up by routine calls to see that it is carried out. If sufficient inspectors were available to the Health Department to conduct these routine tours much more rapid progress and much better sanitary conditions would prevail.

Your committee has had no special problems turned over to it during the last year. We have endeavored to keep abreast with the work of other public health committees. It seems possible that, from time to time during the course of the year, your committee will conduct inspection tours of the various industries in the State similar to the one just described and will thereby keep a more active contact with the Health Department and industry throughout the State, submitting its report annually to the Society.

HARRIS E POWERS, *Chairman*
ALFRED FRECHETTE
ANTHONY E PETERS

Dr Lewin stated that during the national emergency, owing to the great shortage of labor, the practice of sanitation in restaurants, hotels, food stores and industries had been allowed to become alarmingly lax, and that Dr Powers had repeatedly referred to the shortage of public-health inspectors. Dr Lewin moved that the House of Delegates go on record as stating that the sanitation in the restaurants, hotels and the food handling industries of the State are lax. He also moved that the public-health laws of the State be more rigidly enforced, and that the Secretary send a note to the Health Department and to the Governor to that effect. This motion was duly seconded by Dr Sycamore.

The secretary inquired how effective such a step would be. Dr Wilkins replied that such action would probably do little good unless the Legislature could be induced to appropriate more money to hire more inspectors. The city boards of health did not have enough money to conduct all the inspections required by law. The remedy was up to the Legislature rather than to the Governor or the State Board of Health.

The President stated that it might be worth while for the delegates to pass a resolution voicing the opinion of the Society that larger appropriations were needed to make the proper personnel carry out the provisions already in the law.

Dr Sycamore asked if the matter should be referred to the Committee on Public Health. The President answered that the decision could be left to the discretion of the Secretary, who could send a note to the proper authorities. He moved that the Secretary send a note to the proper authorities. This motion was duly seconded and was carried.

Dr Lewin, for the Committee on Officers' Reports, moved that the Report of the Committee on Public Health be accepted.

This motion was duly seconded and was carried.

The report of the Committee on Tuberculosis was then presented by Dr Robert B Kerr.

month. At any rate, it seems obvious that the public enlightenment on psychiatric matters is a field that needs much more attention and can best be carried out by public talks throughout the State by accredited psychiatrists. This obviously implies the need for more well trained psychiatrists throughout the State. At the present time, to my knowledge, specialists in psychiatry outside Manchester and Concord are virtually nonexistent. Despite this fact there is a crying need for such specialists to share the burden of work, which is physically impossible for one or two persons. This indicates the advisability of taking some steps to attract well trained men to the State. In addition to the lack of mental-hygiene clinics, there is a strong need for facilities for the care of the mentally ill in the outlying parts of the State. It is well known that the State Hospital at Concord has been for many years tremendously handicapped by the fact that it is the only institution of its kind. Eventually some expansion of this institution or the erection of similar institutions in other parts of the State will be imperative. In the meantime, however, would it not be possible to establish, at one or more strategic points, modified institutions for the care and treatment of selected benign cases of mental disorder? In some such way the ponderous work of the present State Hospital could be materially reduced.

All these matters will necessarily require quite substantial financial expenditure. Whether or not this can all be taken care of by appropriations by the State is a matter with which I am quite unfamiliar. However, I should like to point out that the United States Government has before its consideration a bill providing for grants in aid to individuals, institutions and states throughout the country for the betterment of psychiatry in general. This should be looked into thoroughly, for I believe that this bill is likely to be passed and that New Hampshire is certainly one of the states in need of such assistance as might be afforded.

In summary, therefore, I believe that the primary need is for a co-ordinator in all psychiatric and mental-hygiene matters in the person of a director or commissioner of mental health, and that from such a department all the pertinent factors could be directed and co-ordinated and any relations with the United States Government could be established.

It is regrettable that this report must be in the nature of a theoretical discussion and not based on any statistical figures, but I believe that my distance from the central problems accounts for this lack. A further suggestion that might overcome such a deficiency is that future chairmen of the New Hampshire Committee on Mental Hygiene might be in more direct and more frequent contact with all the members of the committee, and that all might make a more active and statistical investigation of the requirements for satisfactory progress in this field.

JOHN B. MCKENNA

Dr McKenna then read Dr Baker's letter of March 6, 1946, to Dr Smith, as follows:

Dear Dr Smith

Yes! I am guilty. I resigned and retired and arrived here in San Antonio, Texas, on December 20, 1945. I sincerely hoped not to overlook my obligations but this matter being out of sight was also out of mind. I do not expect to return to New Hampshire before June 1. I do not have the addresses of my associates on the Committee or would write them at this late hour. Suggest you or Lewin write them of the situation and ask one of them to substitute for me.

My personal feelings are that we should get in touch with the National Committee for Mental Hygiene through its medical director Dr George D. Stephenson, 1790 Broadway, New York City, and get suggestions for forming a good strong committee for mental hygiene in New Hampshire. If this committee had an active president and secretary-treasurer and many active influential members willing to pay dues, it would be an agency for great good in New Hampshire. Perhaps it could include the present Social Hygiene Society. This committee could advise and co-ordinate public clinics and help support and influence public attitudes on mental health topics.

Then all state institutions should do what a small institution some years ago, the Laconia State School, did not have the courage or vision to do: put an item in the state institution budget to cover costs of mental hygiene clinics.

Clinics cannot be run for nothing. I think Dr Dolloff had funds left to that institution during the days of the Bancrofts. Father and son Massachusetts has many institutions. All these state institutions carry a heading for mental hygiene in their budgets, and the legislature allows it. If New Hampshire Medical Society approved such a course I am sure it would be a strong influence with the Committee on Appropriations.

I am sorry to be so lame in this matter but with the approval of other members of my committee, I recommend (1) that a New Hampshire Committee on Mental Hygiene be formed (2) that Dr George Stephenson be written to for assistance (3) that this committee advise and co-ordinate mental hygiene activities in New Hampshire (4) that the public on this subject, and (4) that all state institutions for mental defect, disease and derangement including the state school and state's prison, put an item in their budgets for extended mental hygiene work.

Sincerely,
BENJAMIN W. LEWIN

Dr Lewin, for the Committee on Officers' Reports, moved that the Committee on Mental Hygiene take the lead in this field of hygiene clinics, in educating both the public and the lawmakers. This motion was duly seconded.

Dr Clough inquired if the members of the committee could not provide, during the year to follow, a definite motion or program to be presented to the Governor of New Hampshire for funds to be raised for psychiatric clinics.

The President pointed out that there was great need in the State for outpatient psychiatric care and patient care for the people unable to meet the tremendous expense of the facilities available for private care. He therefore wished to hear from the members of the committee regarding a concrete plan for the State.

Dr Lewin, for the Committee on Officers' Reports, accepted the suggestion that the matter be turned back to the committee for a definite report at the next meeting. This was seconded, and the motion was carried.

The report of the Committee on OPA Assistance was then presented, as follows:

Report of the Committee on OPA Assistance

The District Food-Rationing Officer of the OPA called on your committee for advice regarding the need for additional unrationed foods in some hundreds of cases. As restrictions were removed on the sale first of processed foods and then of meats, these requests became less numerous. With the discontinuance of rationing, which we hope may come soon, this function of your committee will be at an end.

In deciding on the merits of so many applications, it has of course been necessary to be somewhat dogmatic. We have followed in the main the recommendations of the Subcommittee on Medical Food Requirements of the National Research Council, but we have tried to give a liberal interpretation.

Your committee early lost one member through removal to another state, and a second member was on duty outside New Hampshire during much of the year. This, together with the more urgent problems caused by rationing, prevented any effective consideration of the overall nutritional situation in New Hampshire. However, your chairman did discuss these matters with Miss Hinman, the state nutritionist, on two or three occasions. In more normal times, which we hope are at hand, such a committee could be of definite value in stimulating interest in good nutrition throughout the State.

There is as much "hidden hunger" in New Hampshire, especially in some rural areas, as in most other parts of the country. Stressing these problems and the best means of dealing with them, discussing them before the state and county medical society meetings and before nursing groups, as well as giving the state nutritionist every encouragement, should in the end be productive of definite results.

COLIN C. STEWART, Chairman
SIMON STOVE

Dr Lewin, for the Committee on Officers' Reports, moved that this report be accepted and

ork harder to be sure of continued reductions in the death rate. We appeal to the members of the Society for their continued aid and co-operation. We urge better and prompter reporting of tuberculosis cases by the practicing physicians to the State Board of Health. (The report slip states that the reports are confidential.) We suggest that the members of the Society request aid when it is needed in the examination of contacts and so forth. We urge further consideration of the practicability of routine chest x-ray examination of patients admitted to general hospitals. In this connection your committee hopes that in the coming year a plan may be worked out for such a study in one or two general hospitals in the State. The findings may be indicative of similar samplings elsewhere and may give more definite information regarding the possible values of such a procedure in New Hampshire.

ROBERT B. KERR, *Chairman*
RICHARD C. BATT

Dr Lewin referred to a point emphasized by Dr Kerr—the advisability of routine chest x-ray study of all patients admitted to general hospitals, but stated that the committee had recently consulted x-ray men and learned that film is still hard to obtain, so that the carrying out of this suggestion for the present seemed impracticable. He added that when x-ray film again became plentiful, however, one or two hospitals in the State should try routine chest x-ray examinations for a year, and the results should be reported at a future meeting of the House of Delegates.

Dr Lewin, for the Committee on Officers' Reports, moved that the House of Delegates go on record as favoring a one-year trial of routine chest x-ray study by two hospitals in the State when x-ray film again became plentiful. This motion was duly seconded.

Dr Sycamore stated that no difficulty in obtaining film had been experienced in his section of the State. He believed that the proposed study would be interesting, but that the question of its economic desirability would depend on the amount of unsuspected disease uncovered by such a survey.

The President asked who would be responsible for the cost of the study.

Dr Dye inquired what hospitals would be selected and by whom.

Dr Sycamore replied that these matters could be worked out by the New Hampshire Tuberculosis Association.

Dr Johnston stated that several Boston hospitals had carried out surveys, which had proved satisfactory.

Dr Clough expressed his belief that the State Hospital could carry out the study.

Dr Sycamore said that the State Hospital was a special type and that perhaps its study would not have as much value as one conducted by a general hospital.

The speaker asked who was to pay for the study.

Dr Lewin answered that Dr Kerr probably believed that the Tuberculosis Association would have something to do with the expense of the study.

A member stated that the Society should approve the general adoption of the study, rather than stipu-

late a trial of approving something that has adequately been proved in other places and thus not contribute anything more than what has been contributed in other places.

Dr Lewin replied that the mention of two hospitals was merely for the purpose of obtaining a report on the experience of those institutions.

Dr Parsons pointed out that some patients routinely admitted to a hospital paid \$10.00 for a chest x-ray film, but that if the State took the x-ray film for \$1.00, the \$10.00 could not be collected.

Dr Biron suggested that, instead of enumerating the number of hospitals, the Society recommend that routine studies be done wherever possible.

The President stated that routine studies should be performed on everybody in the State, and that he believed that the Society should approve in principle universal x-ray studies. He did not, however, believe that the survey should be limited to ordinary patients admitted to general hospitals.

The motion was carried.

Dr Amsden then presented the following report:

Report of the Necrologist

The following members of the New Hampshire Medical Society have died since the last report of the necrologist:

NAME	ADDRESS	DATE OF DEATH
Abbott, Clifton S	Laconia	December 11, 1945

HENRY H. AMSDEN

Dr Lewin for the Committee on Officers' Reports, moved that the report of the Necrologist be accepted. This motion was duly seconded and was carried.

The speaker expressed the Society's thanks to Dr Lewin and his committee for their excellent work. He then asked whether the delegates approved a request from the New Hampshire Department of Public Welfare for the appointment of Dr John A. Coyle to the Medical Advisory Committee of Ophthalmologists.

The Secretary stated that the Department of Public Welfare had a group of six or seven ophthalmologists with whom they consulted regarding cases of blindness, and that the department selected the men it wished to serve on the committee. As a matter of courtesy, they had always asked the Society to ratify or approve the appointments.

The report of the Committee on Tuberculosis was presented, as follows

Report of the Committee on Tuberculosis

Since the appointment of this committee last May one of its members, Dr Rufus R. Little, formerly superintendent of the New Hampshire State Sanatorium, has accepted the position of superintendent of the Bergen County Hospital at Ridgewood, New Jersey. During his service in New Hampshire Dr. Little made an outstanding contribution to the success of the program for the cure and prevention of tuberculosis. As medical director of the New Hampshire State Sanatorium he greatly expanded the service in chest surgery. This program had been ably inaugurated by his predecessor, the late Dr. Robert M. Deming.

Your committee is happy to report that the State has emerged from World War II without evident injury to the health of its people. The death rate from all causes has decreased to a low point. The tuberculosis death rate, which increased slightly in the year 1943, was reduced to an all-time low—18.7 per 100,000 population—in 1945. This rate is one of the lowest among the states of the Union.

It is an axiom accepted by vital statisticians that the trend in death rates from infectious diseases should be evaluated on the basis of analysis by three-year periods. Study of the tuberculosis mortality statistics on this basis demonstrates that the rate has been maintained on a downward basis for the last thirty years, during which an increasingly intensive campaign has been waged against the disease by the medical profession, public-health workers, the state government and the general public.

Further analysis of the tuberculosis mortality statistics by three-year periods discloses that the reductions in the early years of the intensive attack against the disease were large. As the mortality has declined these reductions have decreased, even with the increasing effectiveness of activities for the eradication of the disease. The average annual tuberculosis death rate for the three-year period 1916-1918 was 117.2 per 100,000 population, and in the succeeding period 1919-1921 was 92.7. This represented an aggregate reduction of 25 per 100,000 population. Again studying the three-year period 1940-1942 we see that the annual average tuberculosis death rate was 26.6. In the three-year period 1943-1945 the rate was 23.3. This is a reduction of 3.3. This analysis demonstrates a well recognized fact, acknowledged by vital statisticians and students of communicable diseases, namely, that it requires even more intensive effort to reduce a low tuberculosis death rate than a high one. The irreducible minimum in the death rate from tuberculosis is conjectural. Some public-health authorities estimate it as a rate of 15 per 100,000 population. If the present effective campaign against the disease is continued we should reach this rate by 1954 (based on an annual average rate for the three-year period at that time). The medical profession, however, has adopted as its goal the virtual eradication of the tubercle bacillus, and will press on to that end.

Many members of the profession and workers in the public-health field feared that the onset of the greatest war in human history would bring about a reversal of the reductions in the tuberculosis mortality. This reversal has not occurred. It may be said that several factors contributed to the continued decline in the death rate during the war years, despite longer hours of labor for the people and the strains and stresses, both physical and mental, under which they worked.

First, the population did not have to undergo serious malnutrition or exposure to debilitating diseases. Second, the medical and public-health resources of the State functioned at a high level of efficiency. These resources were greatly augmented by the tremendous increase in chest x-ray surveys conducted for selective-service registrants in the State Induction Center, in the state-wide program of the New Hampshire Tuberculosis Association in its chest diagnostic clinics and in its schools and college tuberculin-test surveys, and in the joint program of the State Board of Health and the State Tuberculosis Association of chest x-ray films for workers in industry.

During the last five years more than 80,000 chest x-ray films have been taken in these various surveys, in addition

to the large number taken in hospitals throughout the State by request of members of the New Hampshire Medical Society.

So much has been said in this report and in previous reports regarding the encouraging reductions in the tuberculosis death rate that it might be thought that the disease has been brought to a point of minor significance in the lives of the people of the State. This is far from the truth, and such an impression might lead to relaxation of the intensive campaign that has been waged against this disease. Such relaxation of effort would inevitably lead to disastrous results, and the ancient enemy, the tubercle bacillus, would again increase its ravages among the people.

The tragic fact remains that even today tuberculosis is the master thief of human lives and efficiency caused by infectious diseases in the State. The tubercle bacillus is still unconquered and a major cause of disease and death.

In the summer of 1945 one of the members of your committee, aided by the Division of Vital Statistics of the State Board of Health, prepared for general distribution a booklet entitled "Tuberculosis Facts and Figures for New Hampshire," which presented a series of tables and graphs illustrating the status of the tuberculosis problem.

Table VIII in the series is entitled "Tuberculosis—The Leading Cause of Death from Communicable Diseases in New Hampshire for the Past Fifteen Years by Five-Year Periods." The chart portrays the tragic fact that in the five-year period 1940-1944 tuberculosis caused 621 deaths, whereas the following number of deaths were caused by other infectious diseases in the same period: whooping cough, 45; infantile paralysis, 23; measles, 18; scarlet fever, 16; typhoid fever, 7; diphtheria, 2; and smallpox, 2. Nor does this table tell the complete story of the ravages of the disease, which is not one of short duration, but an infectious malady disabling the afflicted for many months and often years whether the outcome is cure or death. The vital statistics tell only of deaths. They do not portray the valiant services of the sanatoriums or the courage and sacrifice on the part of the patients and their physicians and nurses that have resulted in the cure and healing of tuberculosis among thousands of New Hampshire's people.

Two years ago one of the members of your Committee made a study of the diagnoses among persons admitted to the chest diagnostic clinics of the New Hampshire Tuberculosis Association. It was found that the physicians of New Hampshire referred to these clinics for final diagnosis the group of people in whom were discovered the largest number of active cases of pulmonary tuberculosis.

Ten per cent of all patients referred to the clinics that year by the physicians had active cases of pulmonary tuberculosis. One hundred and eighty-five out of the 390 practicing physicians in the State referred patients to the clinic.

There is no doubt that the most important of all case-finding agencies in the fight against tuberculosis in the State are its practicing physicians. It is almost always true that the family physician has the first opportunity not only to ascertain the presence of tuberculosis among the people, but also to give battle for the cure of the afflicted and to safeguard the other members of the family from the tubercle bacillus. For it is to the family physician to whom most people go when troubled by signs of ill health.

The records in the chest diagnosis clinics prove that the physicians of the State, if they are determined to do so, can perform a better job of suspecting and discovering active tuberculosis cases, year in and year out, than any other agency.

In the same study of the population of chest diagnostic clinics it was found that the second largest number of significant cases of tuberculosis was found among the contacts. For the most part these persons were referred to the clinics by the tuberculosis nurses, with the approval of the family physicians.

What of the future? There is no preventive for tuberculosis such as medical science has provided in toxoid for diphtheria and vaccine for smallpox, nor is there any specific cure.

We must carry on and intensify our present program of cure and prevention, utilizing to the fullest extent the resources that have already proved to be so effective.

As has already been outlined in this report, we have arrived at the point of diminishing returns for efforts expended in the tuberculosis program—that is, we must

The Secretary stated that the Blue Shield had no schedule and asked if indemnity payments were wanted. Dr Appleton replied in the affirmative.

This motion was duly seconded and was carried. A member moved that since there was no further business the meeting adjourn. This motion was duly seconded and was carried.

Whereupon, the first meeting of the House of Delegates was adjourned at 11 55 p m

CARLETON R METCALF, *Secretary*

* * *

The House of Delegates reconvened at the Hotel Carpenter, Manchester, on May 14, 1946, at 9 00 a.m., with Speaker Deering G Smith, of Nashua, presiding.

The following members answered the roll call

The President, *ex-officio*
The Vice-President, *ex-officio*
The Secretary-Treasurer, *ex-officio*
Samuel Feiner, Ashland
Earl J Gage, Laconia
Francis J C Dube, Center Ossipee
W J Paul Dye, Wolfeboro
Albert C Johnston, Keene
Marjorie Parsons, Colebrook
Israel A Dinerman, Canaan
Leslie K Sycamore, Hanover
Robert E Biron, Manchester
George C Wilkins (alternate for Samuel Fraser), Manchester
Loren F Richards, Nashua
Robert R Rix, Manchester
Deering G Smith, Nashua
Frank J McQuade, Franklin
William P Clough, Jr, New London
Philip M L Forsberg, Concord
Willard C Montgomery, Epping
Samuel T Ladd, Portsmouth
Robert W Tower, Plaistow
William R Latchaw, Somersworth
Raymond R Perreault, Rochester
B Read Lewin, Claremont

The speaker declared a quorum present

The first order of business was the report of the Nominating Committee by Dr Richards, who nominated for President Drs Ralph W Tuttle, of Wolfeboro, Edward R B McGee, of Berlin, and Charles W Hannaford, of Portsmouth

The Speaker asked if any further nominations for President were forthcoming

Dr Biron moved that the nominations be closed. This motion was duly seconded and was carried.

The Speaker appointed Drs Dinerman, Gage and Feiner as tellers

On written ballot, Dr Ralph W Tuttle was elected president

Dr Richards nominated for Vice-President Drs Clarence Dunbar, of Manchester, Robert Holmes, of Keene, and John Hunter, of Dover

The Speaker asked if there were any additional nominations from the floor

Dr. Biron moved that the nominations be closed. This motion was duly seconded and was carried.

On written ballot, Dr Hunter was elected vice-president.

A partial report of the Committee on Amendments to the Constitution and By-laws was presented by Dr Dye, who stated that the committee moved to amend Section 11 of Chapter VIII of the by-laws to create a new standing committee, to be known as the Council of the New England State Medical Societies, consisting of three members

This motion was duly seconded by Dr Biron

The speaker stated that the title of the committee could not be the Council of the New England Medical Societies

Dr Dye expressed his willingness to have the title changed

The Speaker stated that representatives to the council could be chosen

Dr Sycamore pointed out that the representatives were delegates to the council

Dr Wilkins asked what the former name of the group had been. The President replied that the title was given in old records as "New England Council"

The Speaker stated that the present name was the Council of the New England State Medical Societies and that the council could not be created at the meeting. The members from the Society could be called representatives to the council, delegates to the council or members of the council. He suggested the word "delegates"

The Secretary observed that the title had formerly been the "New England Medical Council" but had been changed to the "Council of the New England State Medical Societies". He preferred to list the delegates as members of a standing committee, as the Committee on Medical Hygiene was listed, with the heading, "Council of the New England State Medical Societies"

The motion, as amended, was carried

Dr Dye moved that Section 11, Chapter VIII, of the by-laws be amended to read as follows

The Committee on the Control of Cancer shall consist of five members whose duty it shall be to study conditions in this state and bring to the attention of the Society and of the general public such matters concerning the prevalence, prevention and cure of the disease as may seem to them advisable

This motion was duly seconded and was carried.

The President then moved that the Secretary cast one ballot for the election of the remainder of the slate of candidates. This motion was duly seconded and was carried

The Secretary announced that he had cast the ballot, electing the officers and committees as named on the slate

The Speaker then declared the officers and committees elected to their respective offices for the ensuing year

Dr Dye, for the Committee on Amendments to the Constitution and By-laws, recommended that the proper section of Chapter VIII of the by-laws be amended to discontinue the Committee on Medical Preparedness, and moved the adoption of this

Dr Biron moved the appointment of Dr J Coyle to the committee. This motion was duly seconded and was carried.

Dr Sycamore stated that he had been instructed by the Grafton County Medical Society to ask that Drs Percy Bartlett and Elmer H Carleton be made life members, and moved that they be made life members. This motion was duly seconded and was carried.

The President read the following letter

Dr Richard W Robiosoo, President
New Hampshire Medical Society
79 Lincoln Street
Lacooia New Hampshire
Dear Dr Robiosoo

March 26, 1946

At two recent meetings, the New Hampshire Roentgen Ray Society, which represents all the radiologists in this state, unanimously reaffirmed that x-ray service to hospitals is a professional, not a hospital service. We are particularly opposed to having diagnostic radiology included as a hospital service in Blue Cross policies, because this creates a discriminatory barrier between the radiologist and the other members of the profession. Radiology requires the services of a medical specialist and therefore represents medical practice. Since hospitals are not permitted to engage in medical practice, they cannot legally sell medical radiologic service to an insurance company. No useful purpose can be served by separating the radiologist from the profession and demoting him to the rank of a nonmedical hospital employee.

We believe that the present situation, if allowed to continue, will result in radiologists' abandoning hospital work and confining their activities to private office practice. This would lower the high standards of hospital service and medical care which the New Hampshire Medical Society and the New Hampshire Roentgen Ray Society attempt to maintain.

Upon request of the New Hampshire Roentgen Ray Society I would, therefore, ask you to give me an opportunity to explain our position to the House of Delegates at the next meeting.

Sincerely yours,

(Signed) FRED S. EVELETH, M.D., President
New Hampshire Roentgen Ray Society

BE IT RESOLVED, That the House of Delegates of the New Hampshire Medical Society hereby expresses itself as opposed in principle to any policy whereby the professional services of any doctor of medicine be charged for and dispensed by any other agent than the doctor concerned, and that the House of Delegates is, therefore, specifically opposed to the present system whereby, in violation of their charters, hospitals dispense for fee the services of roentgenologists and pathologists.

The President added that in the report of Dr Smith, as delegate to the American Medical Association in 1939, as presented to the House of Delegates, it was definitely stated that the American Medical Association had gone on record as taking the same position, and that the only permissible basis on which a hospital could utilize this service was that of a payment of money to a patient, with which the patient could recompense the doctor. He moved the adoption of the resolution. This motion was duly seconded by Dr Clough and others.

Dr Sycamore observed that the directors of the Blue Cross recognize the validity of this position, their only question being whether it was practical, because of the fact that radiologists were in hospitals, and patients considered x-ray study a hospital service. He believed that co-operation among the Blue Shield, the Blue Cross and radiologists would settle the issue.

A member stated that if the proposed change were made, the Enabling Act for selling insurance would result in the transfer of physicians to the Blue Shield from the Blue Cross, since participants of

Blue Cross were not allowed to sell professional services of any description.

Dr Biron recalled that at a recent meeting of the New Hampshire Pathological Society this subject had been discussed in a similar manner and that a similar resolution had been adopted. The Blue Cross contract had also taken up some of the diagnostic work in neurology, in which the situation was analogous to that in the laboratory and the x-ray room, the Blue Cross was considering the matter.

The motion was carried.

Dr Parsons then stated that the welfare patient rates in Coos County should be increased.

A member remarked that he had been approached by the members of a county society regarding the fee of \$20.00, which included prenatal care and delivery and which had not been changed since the war, and that he had been asked to inquire what was being done elsewhere—for example, in the large cities.

The President said that he was sure that the Department of Public Welfare was concerned about the situation and that it would like to meet the proper recompense in welfare cases. Two years previously the fee for office and house calls had been definitely increased, and the department had also permitted the addition of medicine up to a cost of \$1.00, without the necessity of listing the type of medicine given. The President further pointed out that many of the state societies were fumbling through the same problem, the answer to which was a provision for service through insurance, using the basic insurance rate under which patients under the plans could get medical care. The greatest hindrance resulted from the fact that the insurance plan had not been accepted throughout the State. Acceptance was necessary before the Department of Welfare shifted its own medical-care burdens onto the shoulders of physicians.

The Speaker stated that he had been informed by the Secretary that the Department of Public Welfare had increased the rates 25 per cent.

A member inquired whether such a fee included prenatal care. The speaker replied in the affirmative.

A member stated that certain welfare organizations simply referred to a fee schedule made up in the days of the depression by a committee headed by Dr Fuller who took into account the conditions at that time, and that some committee should revise the suggested fee schedule to conform to present conditions.

The President recommended that the Society favor the fee schedule that had become a part of the voluntary insurance plan to cover the care of the indigent of the State.

Dr Appleton moved that a fee schedule for indigent patients be made up by the Department of Public Welfare along the lines of and on the same basis as the Blue Shield.

went up at one point to 60 per cent. The patient, however, grew steadily weaker and had more trouble with burning pain in the buttocks and back, although the burning sensation in the feet disappeared. The appetite began to fail, and he had great difficulty in sleeping because of nervousness and the burning sensation. Weakness became so marked that he confined himself to his room. Some fibrillation in the muscles was noted. Although the patient was afebrile, occasional sweats occurred, and he felt warmer than usual. He was finally admitted to this hospital for study.

Physical examination revealed a nervous, depressed, markedly weakened man, with a flushed face and neck. The thyroid gland was palpable but not enlarged. The heart and lungs were normal. The liver edge was felt four fingerbreadths below the costal margin. The spleen was not palpable. There was an area of hyperesthesia over the left buttock. The legs were somewhat weak, with questionable atrophy about the knees.

The temperature was 98°F, the pulse 120, and the respirations 20. The blood pressure was 130 systolic, 85 diastolic.

Examination of the blood revealed a red-cell count of 4,000,000, with a hemoglobin of 70 per cent, and a white-cell count of 2500, with 11 per cent segmented and 20 per cent band neutrophils, 3 per cent eosinophils, 42 per cent small lymphocytes, 12 per cent large lymphocytes, 1 per cent immature lymphocytes, 1 per cent monocytes and 5 per cent blast cells of the white series. The red cells varied in size and showed some polychromasia. Several normoblasts and stippled cells were present. The alkaline phosphatase was 14.4 Bodansky units, the serum phosphorus was 4.2 mg, the cholesterol 154 mg, the cholesterol esters 97 mg, the non-protein nitrogen 23 mg and the total protein 6.84 gm per 100 cc, with 4.4 gm of albumin and 2.4 gm of globulin. The van den Bergh test was normal. The bromsulfalein test showed 50 per cent retention of the dye. The prothrombin time was normal. The urine was normal, showing no bile. Several determinations of the basal metabolic rate ranged from +41 to +23 per cent.

X-ray studies of the chest and pelvis were normal. A plain film of the abdomen showed a normal liver and suggestively large spleen.

The patient spent most of his time in bed because of weakness. The pulse ranged between 100 (while the patient was sleeping) and 120. Frequent injections of Demerol were required to relieve the burning pain in the back and buttocks.

On the fifth hospital day a liver biopsy was performed.

DIFFERENTIAL DIAGNOSIS

DR. WYMAN RICHARDSON: Dr. Castleman was good enough to give me a blood smear to examine, which I did before I looked at the record. This blood smear showed abnormal white cells, to which I shall

return, a total white-cell count that was less than normal, with a relative but not absolute increase of lymphocytes, polymorphonuclear neutrophils, what there were of them, showing definite toxic granules, reduced platelets, in conjunction with the decrease in neutrophils, and occasional heavy polychromatophilic and nucleated red cells.

What can one say of such a blood smear? There was red-cell regeneration, as shown by the nucleated red cells and the polychromatophilic cells. What conditions cause such regeneration? Hemolytic anemia might, but hemolytic anemia and reduced platelets do not occur in the same patient. In other words, hemolytic anemias are associated with leukocytosis and an increase of platelets. Red-cell regeneration follows acute blood loss, in which, again, one finds increased platelets. Red-cell regeneration occurs in bone-marrow encroachment. In such cases the white-cell count and the platelets vary, depending on the cause of encroachment. That brings us back to the abnormal white cells. In the record they are given as 5 per cent. The blood smear disclosed 5 per cent or more immature cells, which I could not identify and which may be called stem cells. That percentage seemed high enough to be significant. There were also some necrotic white cells that, if they had been of the same type, would have increased the percentage, there is no way of determining the type.

The blood picture was quite typical of acute leukemia. Do you want me to discuss the case further?

DR. BENJAMIN CASTLEMAN: That is up to you.

DR. RICHARDSON: I shall just run through the protocol.

The reason for extracting the teeth is not indicated in the record.

The chief symptoms in the history were increasing fatigue and a curious type of burning pain over the buttocks and dorsolumbar region that suggests some sort of nerve-root pain.

The description of the blood is consistent with my findings on examination of the blood smear.

I presume that the heterophil reaction was tested in this case in a search for a benign disease. I am not sure whether the barium enema showed diverticulitis or diverticulosis. There is nothing in the record to suggest active inflammatory diverticulitis.

There was no improvement from liver therapy, because the red-cell count was within the limit of error and both the two red-cell counts and the two hemoglobin determinations were comparable, unless done by a photoelectric-cell technic. Therefore, the patient did not respond to treatment on the basis of the evidence given in the record, but he apparently did not lose ground.

Fibrillation in the muscles does not mean a great deal to me. I do not believe that some type of neuromuscular disease need be considered, such a condition occurs with a loss of considerable weight and tissue of any type.

portion of the report This motion was duly seconded and was carried

Dr Dye then asked the delegates to approve a change, which would subsequently be read before the open meeting, in Article IV, Section 1, of the Constitution to read as follows "Section 1 This society shall consist of members, life members and honorary members" He also asked that Article IV, Section 3, be amended to read as follows "Section 3 Life members shall be those members whose dues are remitted"

Dr Biron moved these changes in the Constitution be approved This motion was duly seconded and was carried

Dr Dye moved that Chapter X, Section 1, of the by-laws be amended to read as follows. "An assessment of \$10 00 per capita on the membership of the component societies is hereby made the annual dues of this society"

This motion was duly seconded by Dr Dube and was carried

Dr Sycamore, stating that it was the duty of the House of Delegates to vote in approval of the Board

of Directors of the New Hampshire Physicians' Service, moved that the House approve the following list of directors Harry L Additon, Monsignor Buckley, O E Cain, Francis J C Dube, Fred Fernald, James W Jameson, James M Langley, Joseph E LaRoche, Carleton R Metcalf, J J Morin, Ray W Pert, Richard W Robinson, C A Rollins, James Ross, Frank J Sulloway, Joseph Winter and L K Sycamore

This motion was duly seconded and was carried

The President expressed gratitude to the Manchester Medical Society for their arrangements of this meeting, and moved a vote of thanks

This motion was duly seconded and was carried

The Speaker asked if there were any further business

Dr Biron moved that the meeting be adjourned This motion was duly seconded and was carried

The second and final meeting of the House of Delegates was adjourned at 9 45 a m

CASE 32391

PRESENTATION OF CASE

A sixty-two-year-old forest consultant entered the hospital because of marked weakness, loss of weight and burning pain over the buttocks and dorsolumbar region

Six months before entry, having previously been in excellent health, the patient noted a sense of fullness in the upper abdomen and put himself on mild dietary restrictions to lose weight Not long after this he noted that he continued to lose weight even though he no longer observed the diet and had a good appetite In the six months before entry he lost 15 pounds Five months before entry he noted excessive fatigue after minor physical exertion and on several occasions felt completely exhausted after an ordinary day's work This fatigability steadily increased until he confined himself to his house and grounds and finally to his room and bed Three months before entry all the

teeth had been extracted A few days later the patient had chills and fever and generalized malaise and felt completely exhausted for ten days A physician discovered that the liver was enlarged, the edge being palpated three fingerbreadths below the costal margin

Examination of the blood at another hospital revealed a red-cell count of 3,900,000, with 12 4 gm of hemoglobin, and a white-cell count of 2350, with 30 per cent neutrophils, 67 per cent lymphocytes, 1 per cent monocytes and 2 per cent eosinophils There was poikilocytosis, anisocytosis and polychromatophilia of the red cells The icteric index was 8 The nonprotein nitrogen was 25 mg, the cholesterol 200 mg, the cholesterol esters 174 mg and the total protein 7 gm per 100 cc, with 4 3 gm of albumin and 2 7 gm of globulin The alkaline phosphatase was 2 5 Bodansky units A heterophil antibody reaction was negative The stools were negative for blood X-ray films of the chest, lumbar spine and pelvis, a gastrointestinal series and an intravenous pyelogram were all reported normal A plain film of the abdomen suggested some enlargement of the liver and spleen A barium enema revealed what appeared to be a mild diverticulitis in the sigmoid area Cystoscopy showed a normal prostate and bladder

The patient complained of a burning sensation in the feet and over the buttocks He was given 2 cc of Lederle's concentrated liver extract twice a week and then once a week, with gradual increase in the red-cell count and hemoglobin to 4,500,000 and 13 gm respectively The white-cell count rose as high as 5600 and the percentage of neutrophils

went up at one point to 60 per cent. The patient, however, grew steadily weaker and had more trouble with burning pain in the buttocks and back, although the burning sensation in the feet disappeared. The appetite began to fail, and he had great difficulty in sleeping because of nervousness and the burning sensation. Weakness became so marked that he confined himself to his room. Some fibrillation in the muscles was noted. Although the patient was afebrile, occasional sweats occurred, and he felt warmer than usual. He was finally admitted to this hospital for study.

Physical examination revealed a nervous, depressed, markedly weakened man, with a flushed face and neck. The thyroid gland was palpable but not enlarged. The heart and lungs were normal. The liver edge was felt four fingerbreadths below the costal margin. The spleen was not palpable. There was an area of hyperesthesia over the left buttock. The legs were somewhat weak, with questionable atrophy about the knees.

The temperature was 98°F, the pulse 120, and the respirations 20. The blood pressure was 130 systolic, 85 diastolic.

Examination of the blood revealed a red-cell count of 4,000,000, with a hemoglobin of 70 per cent, and a white-cell count of 2500, with 11 per cent segmented and 20 per cent band neutrophils, 3 per cent eosinophils, 42 per cent small lymphocytes, 12 per cent large lymphocytes, 1 per cent immature lymphocytes, 1 per cent monocytes and 5 per cent blast cells of the white series. The red cells varied in size and showed some polychromasia. Several normoblasts and stippled cells were present. The alkaline phosphatase was 14.4 Bodansky units, the serum phosphorus was 4.2 mg, the cholesterol 154 mg, the cholesterol esters 97 mg, the non-protein nitrogen 23 mg and the total protein 6.84 gm per 100 cc, with 4.4 gm of albumin and 2.4 gm of globulin. The van den Bergh test was normal. The bromsulfalein test showed 50 per cent retention of the dye. The prothrombin time was normal. The urine was normal, showing no bile. Several determinations of the basal metabolic rate ranged from +41 to +23 per cent.

X-ray studies of the chest and pelvis were normal. A plain film of the abdomen showed a normal liver and suggestively large spleen.

The patient spent most of his time in bed because of weakness. The pulse ranged between 100 (while the patient was sleeping) and 120. Frequent injections of Demerol were required to relieve the burning pain in the back and buttocks.

On the fifth hospital day a liver biopsy was performed.

DIFFERENTIAL DIAGNOSIS

DR. WYMAN RICHARDSON. Dr. Castleman was good enough to give me a blood smear to examine, which I did before I looked at the record. This blood smear showed abnormal white cells, to which I shall

return, a total white-cell count that was less than normal, with a relative but not absolute increase of lymphocytes, polymorphonuclear neutrophils, what there were of them, showing definite toxic granules, reduced platelets, in conjunction with the decrease in neutrophils, and occasional heavy polychromatophilic and nucleated red cells.

What can one say of such a blood smear? There was red-cell regeneration, as shown by the nucleated red cells and the polychromatophilic cells. What conditions cause such regeneration? Hemolytic anemia might, but hemolytic anemia and reduced platelets do not occur in the same patient. In other words, hemolytic anemias are associated with leukocytosis and an increase of platelets. Red-cell regeneration follows acute blood loss, in which, again, one finds increased platelets. Red-cell regeneration occurs in bone-marrow encroachment. In such cases the white-cell count and the platelets vary, depending on the cause of encroachment. That brings us back to the abnormal white cells. In the record they are given as 5 per cent. The blood smear disclosed 5 per cent or more immature cells, which I could not identify and which may be called stem cells. That percentage seemed high enough to be significant. There were also some necrotic white cells that, if they had been of the same type, would have increased the percentage, there is no way of determining the type.

The blood picture was quite typical of acute leukemia. Do you want me to discuss the case further?

DR. BENJAMIN CASTLEMAN. That is up to you.

DR. RICHARDSON. I shall just run through the protocol.

The reason for extracting the teeth is not indicated in the record.

The chief symptoms in the history were increasing fatigue and a curious type of burning pain over the buttocks and dorsolumbar region that suggests some sort of nerve-root pain.

The description of the blood is consistent with my findings on examination of the blood smear.

I presume that the heterophil reaction was tested in this case in a search for a benign disease. I am not sure whether the barium enema showed diverticulitis or diverticulosis. There is nothing in the record to suggest active inflammatory diverticulitis.

There was no improvement from liver therapy, because the red-cell count was within the limit of error and both the two red-cell counts and the two hemoglobin determinations were comparable, unless done by a photoelectric-cell technic. Therefore, the patient did not respond to treatment on the basis of the evidence given in the record, but he apparently did not lose ground.

Fibrillation in the muscles does not mean a great deal to me. I do not believe that some type of neuromuscular disease need be considered, such a condition occurs with a loss of considerable weight and tissue of any type.

It seems probable that a four-hour chart would have disclosed that the patient actually had fever.

It is always difficult, for me at least, to make an adequate study of sensation, even when involvement of the nerves and nerve roots is known, and it is frequently difficult to demonstrate a definite sensory change. Perhaps the hyperesthesia over the buttock can be regarded as definite evidence of nerve-root irritation, which the history suggests.

I interpret all the laboratory tests, except for the alkaline phosphatase, as normal. The result of the bromsulfalein test suggests involvement of the liver. I assume that the liver and spleen were enlarged. It is difficult to settle this point by x-ray examination, in fact, I am not at all sure that even the pathologist can settle it. I suppose when one weighs any organ one still does not know how much it weighed during life, that is, whether it was heavier or lighter. I can conceive of a spleen that could be shrunken or filled up.

It seems to me that a bone-marrow biopsy was indicated and probably would have given as much if not more information than a liver biopsy.

I have very little to add to my original diagnosis. The blood picture is consistent with that of some disease encroaching on the marrow. The clinical findings suggest anemia and weakness and what appears possibly to have been nerve-root pain. Aside from the findings in the blood, the laboratory tests were essentially negative, except for the increased phosphatase and the bromsulfalein retention. There was possibly an enlarged liver, about which the clinicians and the roentgenologist disagreed to some extent. It seems to me that the clinical diagnosis fitted a subacute or acute — although I should call it subacute — aleukemic leukemia, which is my diagnosis. That means that the liver had presumably been invaded. Invasion of the liver by lymphoma occurs quite frequently, late in the disease, but primary invasion with primary symptoms is unusual. I remember a case with severe changes in which the disease seemed to be largely confined to the liver, with such a rapid downhill course that the patient was believed to have acute degenerative disease of the liver. Such a case is unusual, however, and I should say that the patient in the case under discussion had lymph nodes along the paravertebral areas, with possible involvement inside the spinal canal and with pressure on nerve roots, and that he may also have had a diffuse lymphocytic infiltration of the liver. One might also say that there was no disease of the liver, but the results of the bromsulfalein test remain to be explained. The alkaline phosphatase might be accounted for on the basis of disease involving the bone, with osteoblastic activity, or on the basis of liver disease, most frequently seen in biliary obstruction but perhaps occurring oftener in neoplasm than any other condition. I have found, however, that the alkaline phosphatase is not always dependable. I disregarded it in the last case that I

discussed — much to my discomfiture, because the patient turned out to have malignant tumor with biliary obstruction.

The basal metabolic rate makes one think of thyroid disease. The basal metabolic rate is elevated in both leukemia and aleukemic leukemia. The age of the patient, the way in which the disease progressed and the nerve-root symptoms allow me to make a guess regarding the clinical diagnosis — subacute aleukemic leukemia, probably lymphoblastic. Pathological examination probably disclosed a lymphoblastic lymphoma.

DR LAURENCE L. ROBBINS: This point on the difference of opinion regarding the size of the liver and spleen should be straightened out. I interpreted these films, and although I knew that the liver was enlarged clinically, I could not say that it was enlarged from the films. That is not an infrequent discrepancy. The size of the liver in the x-ray films is not too accurate, whereas demonstration of the size of the spleen is much more accurate. So long as the clinical findings are indicative I should not be disturbed if enlargement of the liver did not appear in the x-ray films.

DR RICHARDSON: The liver is often only two or three fingerbreadths below the costal margin, but no mention is made of the upper level of dullness. Frequently the liver is in a low position and is not enlarged. I believe that four fingerbreadths indicates enlargement, and I accept the statement that the liver was enlarged, there is no statement, however, about the upper limit of dullness.

DR JOHN GRAHAM: The upper limit of dullness, as I remember, was below the fifth rib.

DR RICHARDSON: Then the liver was enlarged.

DR N. M. MARTIN: Should you consider the possibility of a reticulum-cell tumor, as opposed to the lymphoblastic type?

DR RICHARDSON: Yes, only I do not believe that the stem cells or immature cells would have appeared in the blood film.

DR MARTIN: They might, if there had been a large amount of spread.

DR RICHARDSON: In such cases the abnormal cells are monocytes, or an actual monocytic leukemia is present. I cannot tell from this blood picture whether or not the cells were monocytes, which usually occur in patients of middle age.

DR EARLE M. CHAPMAN: Is a low white-cell count and lymphocytosis, in the presence of infiltration in the liver of other cells than monocytic cells, possible in leukemia? Such findings are seen in Chian's disease, in which there are focal areas of liver degeneration.

DR RICHARDSON: There are not usually many abnormal cells in the blood. Any patient with a large congested spleen is likely to have a leukopenia, which is often seen in cirrhosis when there is an enlarged spleen. I should not say that actual liver involvement is necessary.

GRAHAM I saw this patient just a week admission, when the suggestive symptoms weakness, loss of muscular strength and pain-taneous sensations, the most prominent symptom being the severe pain in the back and the burning sensation in the buttocks that kept him awake night, despite every attempt to find a sedative relieve him. The impressive point in the physical examination before admission was the con-ly rapid pulse (120), with a normal tempera-ure. Hyperthyroidism might have been considered, use of a lid lag, a flushed face and neck and a irregular pulse. The patient lay in bed in a house with only a sheet over him, but he ned that he was warmer than anyone else in the se. For over three months he was known to e had an enlarged liver. Smears performed at home failed to reveal any abnormal cells, those e when he first consulted a physician showed a white-cell count, with lymphocytosis. The basal abolic rate was +41 per cent. On admission re was a question of changes in the liver resulting m some form of thyrotoxicosis, cirrhosis, car-oma of the liver or leukemia. Pernicious anemia med to be ruled out when there was no response therapy. I observed the abnormal cells in the ear and inclined toward a diagnosis of leukemia. biopsy was done on the liver rather than the bone ellow chiefly because it was easier and was the e organ that appeared to be pathologically fected.

DR. CHAPMAN Was the patient an alcoholic?

DR. GRAHAM No. He took an occasional drink. it was by no means an alcoholic.

CLINICAL DIAGNOSIS

Aleukemic leukemia

DR. RICHARDSON'S DIAGNOSIS

Subacute aleukemic leukemia (lymphoblastic lymphoma)

ANATOMICAL DIAGNOSIS

Aleukemic leukemia (?monocytic or lymphatic), with massive liver involvement

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN An aspiration biopsy taken by Dr. Wade Volwiler was quite satisfactory. Diffusely infiltrating the liver, more marked in the sinuses, were large abnormal cells that I could not identify with certainty, but that were certainly leukemic cells. I thought that cells of the myeloid series could be ruled out. The cells were typical of either the monocytic or the lymphoid type, I rather favored the former, since many cells had horseshoe-shaped nuclei that were more in keeping with that diagnosis. Dr. Graham showed the slide to Dr. Frederic Parker,

Jr., pathologist at the Boston City Hospital, who was also in favor of the monocytic group.

DR. GRAHAM, will you tell us what happened to the patient after the biopsy?

DR. GRAHAM I cannot give a final answer. It was decided to give some x-ray therapy starting over the back, in the hope of relieving the burning pain in the back if it was due to nerve-root infiltration. After the third or fourth treatment, as I remember it, the patient developed jaundice and became extremely sick, so that the benefit from x-ray therapy was regarded as not worth the attending discomfort. In fact the patient decided that for himself

I should like to ask Dr. Richardson what his experience has been regarding the relation of the basal metabolic level and leukemia. Is there any connection with the white-cell count or any other findings?

DR. RICHARDSON Several people have used the basal metabolic rate as a basis for deciding on the necessity of x-ray treatment. The test is difficult to do accurately. It seems to me that one can get along about as well with one's own clinical findings, such as fever, malaise and the blood picture.

CASE 32392

PRESENTATION OF CASE

First admission A twenty-seven-year-old housewife entered the hospital because of urinary drainage from an operative wound.

The patient's health had been excellent until fifteen months before entry, when she noticed crampy pains in the lower abdomen that began shortly after a menstrual period and gradually increased in severity. She was taken to another hospital, where she was told that she had pelvic trouble and given intensive treatment with penicillin and sulfonamides, to some of which she was sensitive. After a month of this regime a laparotomy revealed bilateral tubal abscesses, with leakage of pus from the left tube. The tips of both ovaries, which were likewise diseased, were resected along with the tubes. Following the operation, the patient noted that when she was given an enema there was leakage from the suprapubic wound, usually consisting of purulent material, but that fecal matter seemed to be extruded when the bowels were loose. Two months before entry a second operation, which was performed to remove the sinus tract, revealed that the bladder was also involved, postoperatively, urine, as well as fecal material, drained from the suprapubic wound. The drainage of urine was particularly profuse when natural voiding was delayed. Although the appetite had returned somewhat, at the time of admission the patient weighed 80 pounds, as compared to her usual 123 pounds. She also had difficulty with postprandial gas and constipation.

Since the onset of her illness she had lost a considerable quantity of hair, and much of what remained had turned gray. The patient had been married five months before she was taken ill. There was nothing in the history to indicate venereal exposure.

Physical examination revealed a poorly nourished woman in no acute discomfort. The heart and lungs were normal. The abdomen showed a palpable nontender mass low in the left lower quadrant. The old midline scar appeared well healed, but along the recent low suprapubic incision there were two draining sinus tracts surrounded by granulation tissue. There was slight clubbing of the fingers and toes.

The temperature was 99.5°F, the pulse 95, and the respirations 20. The blood pressure was 120 systolic, 75 diastolic.

Examination of the blood revealed a hemoglobin of 10.0 gm and a white-cell count of 21,400, with 79 per cent neutrophils and 17 per cent lymphocytes. The total protein was 5.7 gm per 100 cc, with 3.3 gm of albumin and 2.4 gm of globulin. The nonprotein nitrogen was 15 mg, the sugar 90 mg, the calcium 8.8 mg and the phosphorus 4.1 mg per 100 cc. The carbon dioxide was 25.8 milliequiv per liter.

The urine showed a +++ test for albumin, with a few red cells and 250 white cells in clumps per high-power field. Repeated cultures grew colon bacilli and nonhemolytic streptococci.

An intravenous pyelogram revealed slight embarrassment to drainage on the left side but no other abnormality of the upper urinary tract. There was some irregularity of the left side of the bladder, and dye seemed to be escaping, from either the bladder or the left lower ureter, into the surrounding soft tissue and possibly into the bowel. An x-ray film of the chest revealed no evidence of active parenchymal disease, but a few prominent markings in the left first interspace were suggestive of old scars. A barium enema was not entirely satisfactory because of the patient's inability to retain enough barium to fill more than the rectum. The bowel above the level of the sigmoid was widely filled with retained gas and fecal material. At the level of the rectosigmoid, barium escaped into a sinus tract, the destination of which could not be determined.

On the ninth hospital day a transverse colostomy was performed. The patient recovered uneventfully.

Second admission (four months later). The patient showed little or no improvement after discharge. Drainage continued from the sigmoid fistula, producing a thin purulent material rather than feces.

Physical examination and laboratory findings were essentially unchanged from those of the previous admission. On the fifth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. RICHARD CHUTE. This previously healthy woman had been married for five months when she

started to have crampy lower abdominal pains beginning shortly after a catamenial period and increasing in severity so that she was taken to hospital where she was given a month's treatment with penicillin and sulfonamides, apparently with no improvement, since she had to be operated on. At operation bilateral tubal abscesses were present, with leakage of pus from the left tube. The tips of both ovaries were also diseased and were resected along with the tubes.

Although tuberculosis is the cause of only 1 per cent of all cases of salpingitis, that disease seems likely in this case, since the process was acute, with pus draining from at least one tube, even after a month's intensive treatment with penicillin and sulfonamides. This treatment would have been enough to improve greatly any salpingitis due to the gonococcus and would probably have made operation unnecessary. Also, there was nothing in the history to indicate venereal exposure. Other evidence of tuberculosis is that x-ray examination of the chest revealed old healed tuberculosis. Although these x-ray findings were not extensive, there was clubbing of the fingers, suggesting extensive chronic pulmonary disease.

After operation a fistula draining sometimes pus and sometimes feces developed and persisted for more than a year. The fact that it persisted so long without healing suggests that it was due to a chronic disease with little tendency to heal, to a partial obstruction of the intestine distal to the fistula or to the intermittent filling up and spontaneous drainage of an abscess connecting with the bowel, such as might occur with diverticulitis of the sigmoid. The patient was rather young for diverticulitis, but tuberculosis could well account for this condition. If the tubes and ovaries were tuberculous and one tube was leaking frank pus, a tuberculous peritonitis with bowels matted with dense adhesions may have occurred. In such a situation a fecal fistula could easily have been caused accidentally during surgery, or a tuberculous lymph node may have broken down, with abscess formation and a fecal fistula that was kept open by partial blockage of the intestine by a tuberculous peritonitis. Nothing is said about sulfur granules to suggest actinomycosis, and I would not expect endometriosis to give this picture, especially starting from a salpingitis.

Two months before entry an operation not only failed to cure the fecal fistula but also created a urinary fistula. The record states that the bladder was involved, but whether by adhesions or by some active disease is not indicated. One can well imagine that the pelvis was a tangled mass of dense adhesions about a purulent fecal draining sinus, with destruction of all normal anatomy, and that a urinary fistula was accidentally created during surgery. The two months' duration of the fistula was rather long for involvement of the bladder, unless some obstruction to urination existed, which is unusual in a

n, or unless tuberculosis of the urinary tract present, which I am inclined to believe was not the case. The urine showed a +++ test for albumin, with a few red cells and many white cells in high-power field, but the source and therefore the significance of the white cells in the urine is in doubt, since it is not stated whether or not this was a catheterized specimen. It is well known that in the voided urine may contain many white cells from the vagina whereas a catheterized specimen from the same person may show no white cells, in the presence of a urinary fistula, some white and a few red cells would probably have been present, even in a catheterized specimen. The red urine cultures showing a mixed infection of colon bacilli and nonhemolytic streptococci are somewhat against urinary tuberculosis, in which the urine frequently gives a negative culture for the ordinary organisms. Furthermore, there was no history of dysuria or frequency, which usually occurs in urinary tuberculosis, and the intravenous pyelograms were normal. Therefore, I am inclined to believe that tuberculosis of the urinary tract did not exist. In contradistinction to bladder fistulas, those arising from the lower ureter often persist for a long time. On the basis of the x-ray film showing irregularity of the left side of the bladder, slight embarrassment to drainage of the left ureter and escape of the dye from the bladder or the left lower ureter into the surrounding soft tissue, and also because of the history that the drainage of urine was abnormally profuse when natural voiding was delayed, I suspect that in the region of the left ureterovesical junction there was an opening not only into the bladder but also into the lower part of the left ureter.

On admission there was evidence of marked weight loss, anemia, a slight fever and a white-cell count elevated to 21,000. I can find nothing in the laboratory studies that does not fit in with this picture of cachexia and infection or that is of any particular significance in the differential diagnosis. The patient was having difficulty with postprandial gas and constipation, which is consistent with the diagnosis of tuberculous peritonitis. A nontender mass was palpable in the left lower quadrant. This, with the loss of weight and anemia, naturally raises the question of cancer. I prefer to explain the patient's clinical findings on the basis of one disease, however, and therefore guess that this mass was inflammatory and tuberculous.

Following the transverse colostomy the fistula, which the history revealed to be in the sigmoid, did not heal in four months. This may well have been due to obstruction distal to the fistula in the sigmoid caused by the tuberculous inflammation and mass. In fact, obstruction in this area was suggested by the x-ray report that the bowel above the level of the sigmoid was widely filled with retained gas and fecal material.

In conclusion, my diagnoses are healed pulmonary tuberculosis, tuberculosis of both fallopian tubes and of both ovaries, tuberculous peritonitis, with fecal fistula of the sigmoid, urinary fistula in the region of the left ureterovesical junction, and nontuberculous cystitis.

CLINICAL DIAGNOSIS

Vesicosigmoidal cutaneous fistula

DR CHUTE'S DIAGNOSES

Tuberculous salpingo-oophoritis, bilateral
Tuberculous peritonitis, with sigmoidal fistula
Urinary fistula left ureterovesical junction
Cystitis, nontuberculous
Pulmonary tuberculosis, healed

ANATOMICAL DIAGNOSES

Tuberculous salpingo-oophoritis
Tuberculous peritonitis, pelvic
Vesicosigmoidal cutaneous fistula

PATHOLOGICAL DISCUSSION

DR BENJAMIN CASTLEMAN. At operation the surgeon, Dr Robert R Linton, found the bladder, uterus, adnexa, sigmoid, cecum and appendix fairly well matted together. The rest of the abdominal cavity was free from adhesions. There was a large granulating area in the left side of the pelvis that extended from the suprapubic sinus tract through the broad ligament and to the side of the sigmoid, where a fistula was demonstrated. The left tubo-ovarian mass was removed, and the fistula repaired. An abscess containing about 50 cc of pus was encountered in the right broad ligament close to the appendix. The abscess was drained, and the appendix removed. This raised the question whether the whole process had originated in the appendix. A suprapubic tube was inserted into the bladder, and the wound closed.

Microscopic sections of the tubo-ovarian mass and serosa of the appendix showed active tuberculosis. Postoperatively the patient continued to drain a small amount of pus from the suprapubic wound and was transferred to a sanatorium.

DR ROBERT R LINTON. In my opinion this case illustrates one of the tragedies of surgical treatment of pelvic inflammation, as well as the importance of obtaining material for microscopic examination to establish a diagnosis. When I first saw this patient I did not even think of tuberculosis. I must commend Dr Chute on his excellent discussion of this case, which he analyzed almost perfectly. I had assumed that the vesicosigmoidal skin fistula, which had resulted from the two previous operations carried out at another hospital, was due to an error in surgical technic. The purpose of the defunctioning transverse colostomy was, of course, to divert the fecal current so that a definitive type of operation could be carried out in the pelvis after the

inflammation had subsided. The patient did not improve so much as I had hoped following this operation, but it seemed advisable to proceed with an attempt to close the sigmoid and vesical fistulas. At operation on the pelvis I was unable to visualize anything in the gross that suggested tuberculosis, there was so much secondary infection in the inflamed and ulcerating areas that there was nothing diagnostic of tuberculosis. I made what I thought was a satisfactory closure of the sigmoid fistula, but as follow-up barium enema studies showed, there was still a fistulous tract connecting the pelvis with the sigmoid. This may have been due to the fact that my suture line did not stay closed, or possibly there was another fistula that I did not find.

In view of the x-ray evidence of the persistent fistula it was obvious that the transverse colostomy could not be closed at that time. It was considered

advisable to send the patient to a sanatorium to attempt to build up her physical condition and give the tuberculous process a chance to quiet down. It was hoped that at a later date, after the pelvic inflammatory condition had become arrested, it would be possible to close the transverse colostomy. It may be necessary, however, before doing this to do a complete hysterectomy, with removal of the other tube and ovary. Despite the fact that I did not make a diagnosis of tuberculous salpingitis I do not believe that the plan of treatment would have been changed very much if the diagnosis had been made prior to my second operation. Radical removal of the uterus and adnexa would have been an extremely hazardous procedure in view of the marked secondary infection due to the connection of the sigmoid and vesical fistulas with the pelvis.

ETHER CENTENARY

THE *Journal* has previously commented on this, the year 1946, as marking the close of a century since anesthesia was introduced to the world as a necessary prelude to major surgery, the demonstration having been made at the Massachusetts General Hospital. Elsewhere in this issue may be found a complete program of the centennial exercises. A century of medical history has given its verdict that the distinction of first appreciating the significance of surgical anesthesia is peculiarly the property of the Massachusetts General Hospital, and it is appropriate that the hospital's outstanding tradition should be based on this discovery.

The occasion of the Ether Centenary is a particularly appropriate one, moreover, at which to present the immediate financial needs of the hospital to the public that it has served so well. These needs are four, comprising a fund to provide a building for the Massachusetts General Hospital Institute of Medical Science, the Massachusetts General Hospital Research Fund to implement this institute, the General Fund to provide for the innumerable expenses of the hospital's operation and the McLean Research Fund to enable the Scientific Research Department of McLean Hospital to further its research in the field of brain diseases and their cure.

The following quotation from an address reprinted in the October 14, 1815, issue of the *Columbian Centinel* seems pertinent at this juncture.

It is not intended to solicit donations by private application to individuals. All good citizens who shall read the address will feel it their duty to contribute in proportion to their ability and will require no further solicitation. The public attention is earnestly called to the facts contained in this address.

And who would be left unmoved by the final paragraph of the address?

To the People of the Commonwealth of Massachusetts

Fellow Citizens

Besides the Undersigned are willing to confess, that they are not ambitious of being the guardians of a charity merely nominal, they are satisfied that the sum, affixed by the Legislature as the condition of its grant, is so small, when compared with the wealth of individuals and the greatness of the state, that no plea, arising from "the hardship of the times," "the general embarrassment of affairs" or "claims of other charities," can or ought avail the community. If such a proposal as this fail, it will be in the judgment of the undersigned, decisive of the fate of the establishment. It will then be apparent, that the will is wanting in the public, to patronize such an undertaking, and that the honor of laying the foundation of a fabric of charity, so noble and majestic, must be left for times, when a higher cast of character predominates, and to a more enlightened and sympathetic race of men.

HOSPITAL SURVEY AND CONSTRUCTION ACT

ORGANIZED medicine will in general welcome the provisions of the Hospital Survey and Construction Act, recently signed by President Truman, as indicated by the support of such organizations as the American Medical Association and the American Hospital Association during the period when the legislation was under consideration in the Senate as the Hill-Burton Bill. For the first time in American history, a balanced and inclusive program providing for a better distribution and an improved quality of hospitals has been established, and this program involves no undue extension of governmental control to private practice.

The act authorizes the appropriation of \$375,000,000 for the construction of hospitals and health centers during the next five years, as well as \$3,000,000 for state-conducted surveys of need. The share of each state in the appropriation for the survey and the construction program will be determined on the basis of population and per-capita income, with the qualification that federal funds may not exceed a third of the total cost of any project. The state must present to the Surgeon General of the United States Public Health Service a plan for construction based on a survey conducted by a single state agency and must appoint a properly qualified advisory council to consult with that agency. Approval of any project depends on sufficient evidence that two thirds of the total cost of construction is available from other than federal sources and that financial support is adequate to maintain and operate the institution after completion. The state is granted latitude to develop and administer its program under standards specified by the Surgeon General and the Federal Hospital Council, which consists of eight members appointed by the Federal Security Administration.

Some of the shortcomings noted by Goldmann¹ in his cogent analysis of the Hill-Burton Bill remain in the act, but there is some question whether these disadvantages are not blessings in disguise. Thus, requirements concerning standards of operation of the hospitals to be constructed are not enumerated, the fees to be charged by participating physicians are not specified, and the amount of the appropria-

tion appears small in view of immediate needs for additions and replacements of hospital buildings. The problem involved is as old as Aesop's King Log: how much — or how little — government is best for the governed. As pointed out in a previous issue of the *Journal*,² the inadequacies of the distribution of medical care are a legitimate concern of government, but the nature of medical standards and the fees to be charged for medical services are matters that are better left to the medical profession, the appropriation, although small in comparison with the billions usually associated with federal grants and agencies, should prove sufficient, when augmented by state funds, to provide for the construction envisaged by the act. These shortcomings offer a challenge and an opportunity to physicians, who by individual and concerted action can render federal definitions, regulations and immense appropriations unnecessary.

NOTICES

NEW ENGLAND DERMATOLOGICAL SOCIETY

The regular meeting of the New England Dermatological Society will be held in the Skin Outpatient Department of the Massachusetts General Hospital on Wednesday, October 9, at 2:00 p.m.

NEW ENGLAND HOSPITAL FOR WOMEN AND CHILDREN

The monthly clinical conference and meeting of the staff of the New England Hospital for Women and Children will be held on Thursday, October 3, in the classroom of the Nurses' Residence at 7:15 p.m. There will be a discussion of unusual post-partum complications. Dr. Bernadette M. Ryder will be chairman.

THE ONE HUNDREDTH ANNIVERSARY OF THE FIRST PUBLIC DEMONSTRATION OF ETHER ANESTHESIA

October 14, 15 and 16 — Massachusetts General Hospital

The Registration Desk will be located in the Rotunda of the Moseley Building at the hospital and all who attend the meetings or the symposiums are requested to register. Information about the various meetings, luncheons and evening functions, as well as tickets, will be obtainable at this desk.

All scientific symposiums will be held at the hospital. The medical public and the general public are cordially invited to attend, no tickets are required, and admission is free.

Those wishing to attend the House-Pupil Alumni Dinner at the Copley-Plaza Hotel should obtain tickets in advance, preferably by mail on the forms that have been sent out for this purpose. These tickets can be picked up at the Registration Desk, and if advance reservations have not been made, reservations and tickets can be obtained at the Registration Desk up to 3:00 p.m. on Monday, October 14. Attendance is limited to house-pupil alumni.

Tickets for the Wives' Dinner held the same night at the Hotel Somerset may also be obtained at the Registration Desk.

Luncheon will be served each day at the hospital for all those attending the symposiums, and on Wednesday, October 16, the luncheon is, in addition, for the house-pupil alumni and their wives.

Applications for tickets to Massachusetts General Hospital Theater Night on Tuesday, October 15, may be reserved by writing to the Ether Centenary Committee at the hospital prior to October 8. These tickets can then be obtained at the Registration Desk. The medical public and all friends of the hospital are cordially invited to this theater performance.

Admission to the Sanders Theater exercises in Cambridge on Wednesday, October 16, at 8:15 p.m. is by invitation only.

A commemorative motion picture of the history of the development of ether anesthesia and methods of manufacture of ether will be shown daily at the hospital and is open to all those attending the meetings.

A THERAPEUTIC SCORE CARD FOR RHEUMATOID ARTHRITIS*

A Standardized Method of Appraising Results of Treatment

OTTO STEINBROCKER, M.D.,† AND ALFRED BLAZER, M.D.‡

NEW YORK CITY

CLINICAL experience and the lack of some accepted system in the literature impressed us with the need for a standardized scheme of appraising therapeutic results in chronic rheumatoid arthritis. We therefore devised the method now used in the Arthritis Clinic of Bellevue Hospital, the so-called "Therapeutic Score Card," which offers an objective and comparatively accurate method of measuring the response to therapy.

One purpose of such a scheme is, so far as possible, to divest therapeutic study of the subjective influence of the patient and of the prejudicial enthusiasm of the physician. Another is to provide a uniform method that can be employed periodically—for example, once a month—on each patient and rapidly enough to be practical and accurately enough to be reliable.

METHOD

The underlying principle of this system is to employ the chief features of rheumatoid arthritis and their response to treatment in determining the effectiveness of any therapeutic agent. To provide an accurate procedure, percentage values are accorded each of the characteristics of the disease, which are tabulated so that exact calculations can be noted and comparisons made.

The scheme is essentially a debit not a credit system. When a patient is first seen all the rheumatoid factors enumerated are noted, and for each one a debit is tabulated. This debit is actually the deduction to be made from a theoretical 100 per cent that represents the status of a recovered or healthy person. If a patient shows inflammatory swelling of the joints, a 50 per cent deduction is entered under the column entitled "Joint Swelling." If the sedimentation rate is elevated, a 15 per cent debit is recorded, and so on down the line of symp-

toms and signs. The patient's debits are then added across the sheet, and the sum deducted from 100. The remainder is scored in the column labeled "Total." Accordingly, a patient first seen may give a balance or total of 35 or 75 per cent, or whatever it may be, signifying a corresponding degree of freedom from rheumatoid disease. In the same fashion at regular intervals, preferably monthly, the therapeutic score is calculated.

As the treatment continues, it is possible by a glance at the record to determine the fluctuations in the patient's rheumatoid status and to discern trends toward improvement or unresponsiveness with an exactness that is calculated and not dependent to any extent on the vagaries of memory, impressions of the patient or the attitude of the observer toward the method of treatment under study. In carrying out therapeutic investigations in this disease, observations are more objective when treatment is prescribed by one person and the calculations made by another, although this method lends itself to reliable estimations by different observers owing to the standard criteria.

At the initial examination it is advisable to note detailed information on all the factors listed. This information serves as the basis of comparison from which all future estimates of progress are derived. The activity of the rheumatoid disease is then assessed and tabulated according to the severity of the features enumerated. After due deliberation we believe that the predominant clinical factors reflecting the activity and progress of rheumatoid disease are joint swelling, sedimentation rate, articular mobility, joint tenderness, weight gain (or loss), hemoglobin (or red-cell count), pain, well-being and functional capacity. Of course the selection of such factors is to some extent a matter of arbitrary decision.

After careful study of our series of rheumatoid patients the criteria were selected and given percentage values determined by much experimental calculation of the factors in the history and course. The features enumerated, we believe, offer a well

*From the Arthritis Clinic, Bellevue Hospital, Fourth Medical Division, New York University.
Presented in summary at a meeting of the New York Rheumatism Association, November 10, 1945.

†Attending physician and chief, Arthritis Clinic, Bellevue Hospital.
‡Assistant clinical professor of medicine, New York University.
§Clinical assistant physician, Bellevue Hospital.

rounded insight into, and evaluation of, the rheumatoid status. As a matter of fact, a difference of opinion regarding the relative importance of several of these items is probably immaterial, so long as specific criteria are chosen and consistently followed throughout in all patients included in a report. The chief principle in the scheme remains that a uniform method of assay is employed and generally accepted, for such a project some criteria must be selected. Obviously the features of rheumatoid disease are not of equal clinical and pathological significance. The relative importance attached to the various characteristics is considered under the discussion of each.

CRITERIA OF IMPROVEMENT

Joint Swelling

Joint swelling is the crucial sign of the rheumatoid process.¹ Unlike tenderness, motion and pain, joint swelling is the most objective index to the patient's progress, of all symptoms, it is also the least affected by emotional influences, voluntary or otherwise. No matter how mild the condition appears or how well the patient seems to be doing, so long as any active inflammation, as evidenced by joint swelling, is present, the patient is suffering from active rheumatoid disease that may flare up at any time or assume a progressive, unfavorable course. For these reasons, before therapy is begun, an initial deduction of 50 per cent for active joint swelling under any circumstances is made. Such a debit makes it impossible for a patient to be classed as recovered or even greatly improved so long as any active articular enlargement persists.

The purpose of these ratings is usually to evaluate the effect of some remedy on the disease. From the therapeutic standpoint, the initial condition is the basis on which the maximum deduction is made.

The amount of swelling is estimated and measured, if possible, at the first examination. The joint most affected is used as the standard. When another joint becomes involved more actively, it becomes the critical one. Regardless of other signs of improvement, any degree of active inflammatory swelling of a joint remains indicative of a persistent rheumatoid process. In the presence of active articular swelling, no matter how slight, no deduction less than 40 per cent is made. Such an allowance indicates that some improvement in the swelling has occurred, but that the continuing inflammatory enlargement remains a serious indication of activity and is as likely to be associated sooner or later with a flare-up as with complete resolution. The importance attached to active joint swelling is a measure of the optimism with which results are regarded — and of their final accuracy. From that attitude, we believe, arise many of the favorable, and ultimately disappointing, opinions on various methods of treatment.

Naturally, the indurated swelling of residual postinflammatory thickening or chronic effusive

synovitis must be differentiated and not given undue significance. Similarly, in elderly patients cardiac or nephritic edema of the ankles and feet should not be mistaken for rheumatoid swelling. The tender lymphedema of the ankles and feet of older rheumatoid patients with varicosities and deep thrombophlebitis, as well as the postural edema of the lower extremities seen in wheel-chair patients and in those who keep their feet over the edge of the bed for long periods, must be recognized.

Erythrocyte Sedimentation Rate

This test is accorded a debit of 15 per cent when sufficiently elevated. The sedimentation rate thereby receives a higher rating than the remaining rheumatoid features. In estimating the significance of the sedimentation rate, we have borne in mind the difference of opinion regarding both the interpretation of a persisting increase in apparently covered patients and the importance of this test compared with joint swelling and other characteristics of the disease. The use of the score card in a series of cases indicates that the sedimentation rate has been given a place proportionate to its clinical role.

Rates of 15 mm by the Cutler method and 75 mm by the Westergren are taken as bases. In other words, if a patient first exhibits an increased rate at or above those points 15 per cent is deducted. In the course of time if the rate goes above the levels, no further deduction is made, because the total debit possible for abnormality of erythrocyte sedimentation is already represented. If the rate falls drops, all or part of the 15 per cent is allowed proportion to the decrease from the original high.

If the record at first shows a sedimentation rate of 75 mm (Westergren method) and a rate of 15 mm at the next determination, 75 per cent is allowed for the improvement so that the score card then registers a deduction of 75 instead of 15 from the original 15 per cent in that column. The score can be scaled according to the same principle for sedimentation rates performed by other techniques.

In the rare cases in which the patient has a normal sedimentation rate to begin with, in the presence of definite clinical signs of rheumatoid activity, a debit is charged for the test. Similarly, when a patient completes treatment and the normal rate remains unchanged, no allowance or deduction is made. In fact, none of the initially normal elements of rheumatoid activity that remain unaltered enter into the calculations. Thus, such signs do not in any way influence the estimate of the patient's response to treatment, which is based on the other abnormal factors manifested. If, on the contrary, a patient appears with a normal sedimentation rate in the presence of other positive signs and finally shows no response to treatment and still presents an elevation of the sedimentation rate at the last examination, the 15 per cent is, of course, charged.

increase the total debit and to show that the patient's condition is worse, at least to the extent indicated by the elevated rate. These are common-se applications of the same principle and are duly acquired by repeated interpretation of the usual picture in these arithmetical terms.

Joint Motion

Joint mobility is given only one twentieth of the significance of the over-all picture — in other words, per cent. Although articular motion occupies an important place in the activities and in the improvement of the patient, the joint inflammation that is usually present so frequently determines articular function that motion is regarded as secondary. At times patients with rheumatoid activity without demonstrable joint swelling suffer some disability. The safer emphasis is considered to be on joint swelling, without completely ignoring joint motion. The improvement of joint mobility, which is rated according to its progress from the original limitation, goes from a debit of 5 per cent to 0 if complete motion is restored, or any part of 5 per cent dependent on the degree of recovery of function.

In severe rheumatoid disease, limited motion or ankylosis is sometimes due to fixed and irreversible changes, such as destruction of cartilage, fibrous or bony ankylosis and subluxation. Naturally, the rheumatoid status should not be discredited because of these conditions. Even if medical treatment is effective, it can only arrest the activity of the disease and cannot improve the irreparable changes and resulting loss of function.

Joint Tenderness

Joint tenderness, like joint mobility, is usually so intimately associated with articular swelling and inflammation in rheumatoid disease that a distinction is almost superfluous. There are patients without definite joint swelling, however, who present joint tenderness as the earliest symptom. There are others in whom the joint swelling has disappeared and whose only evidence of articular involvement is the tenderness elicited by palpation. In such cases slight or great additional features of rheumatoid activity are apparent. So long as the periarticular tenderness persists (especially when compared with palpation of the opposite or other normal or recovered joints), it is best regarded as a sign of continuing activity and given a debit of 5 per cent if unchanged, or any proportion thereof in relation to the initial tenderness. Of course it is essential to distinguish the soreness due to post-rheumatoid periarticular thickening or fibrositis that may no longer signify rheumatoid activity but secondary terminal changes.

Spindle-shaped joints are pathognomonic of rheumatoid arthritis. In some cases, of course, even after the disease is arrested the spindle-shaped deformity persists. The tenderness about such joints

must be carefully evaluated to rule out irreversible periarticular changes as the source of the soreness. If the other signs of rheumatoid activity have resolved, it is safe to assume that in all likelihood the soreness is due to secondary changes. When tenderness continues unduly as a lone symptom, emotional factors must be evaluated. Generalized hyperesthesia should be excluded. Occasionally the previously involved joints become the outlet for psychogenic disorders, complicating the chronic picture and clouding the signs of recovery even after objective signs have disappeared. Pseudoankylosis may be simulated by the same factors, particularly by fear of using joints previously painful on motion.

Hemoglobin

A lowered hemoglobin level is characteristic of most patients with active rheumatoid disease. It becomes, therefore, a fundamental feature of the rheumatoid process. The upper normal value is considered to be 13.5 gm per 100 cc (85 per cent). The hemoglobin is charted at the first examination. If it is above 80 per cent it is considered normal, if it is below 80 per cent, a deduction of 5 per cent is made. If the hemoglobin rises during the course of treatment, a portion of this 5 per cent is reduced according to the degree of improvement toward the normal base. If the hemoglobin remains unchanged at the end of treatment, the same debit is charged, influencing the record of the over-all response of the patient.

Weight Loss

Weight gain is widely accepted as proof of improvement in the patient's general condition when accompanied by other evidence. Avoiding alone is no measure of a satisfactory state, because many patients with active rheumatoid arthritis are overweight. In the usual, asthenic, underweight subject, however, weight gain can well be used as a gauge of response to treatment. In such an underweight patient, provided weight loss has already been noticed during the period of illness, a debit of 5 per cent is made at the outset of treatment. If the patient later shows a gain of more than 1 pound, proportionate credit is given up to recovery of the average weight before illness, which rates a full allowance of 5 per cent.

Pain

Pain represents one of two symptoms included in the score sheet that are purely subjective and in their entirety are given 10 per cent, or one tenth, of the over-all significance of symptoms and signs. Subjective factors are intentionally relegated to a minor place, because they are regarded as the most misleading items in any attempt to arrive at an accurate evaluation of therapy, and are included only because of their widespread use in the literature. To exclude them would probably delay general ac-

ceptance of a standardized method of evaluating therapy. There are enough objective features of rheumatoid disease, as shown in the score card, to guide the assay of any method of treatment without depending too much on the patient's reactions. It is obvious that when joint swelling is improved, joint motion and tenderness ameliorated, relief of pain and a greater sense of well-being almost invariably follow. We have compromised, nevertheless, to the extent that largely subjective responses to treatment are allowed 10 per cent, half of which is allotted to pain.

Even pain can be placed on a more or less objective basis if the patient is initially instructed to take some analgesic, such as aspirin or another salicylate. Some patients are so resigned to their chronic ailment that they prefer to be stoical, in such cases it is gently but firmly insisted that they take medication in adequate doses for relief of pain. In that way, the number of salicylate tablets required daily in the course of time serves as a somewhat objective estimate of the intensity of pain. The initial 5 per cent debit can be scaled down in proportion to the lessening of pain. Loss of sleep due to pain also throws a revealing light on its severity if insomnia is eliminated, at least half the original debit is canceled. The patient's emotional make-up is important in the evaluation of subjective factors, and the examiner must be guided accordingly. The trend of pain response over a period must be taken, and the transient influence of weather and humidity discounted.

Well-Being

The well-being of the patient, which represents an estimate of general subjective response to treatment, includes such factors as mental attitude, loss of anxiety, cheerfulness, confidence, desire to return to some or all of the previous duties and renewed interest in various social activities. Also included are a variety of minor symptoms, which are more or less dependent on some of the features already described and are mentioned merely to outline the scope of this symptom, such as increased appetite, reduced or absent sensations of chilliness and vasomotor disturbance. The interpretation of this phase of the clinical picture depends greatly on the sound judgment of the observer. It is so lacking in objectivity and so reliant on many intangible factors in one way or another that it is allowed only 5 per cent.

Functional Status

The functional status of the patient, to a variable extent, reflects fluctuations in the rheumatoid condition. When increased function arises directly from resolving articular inflammation, the change is adequately registered by improvement in swelling, tenderness and motion. For that reason only 5 per cent is allowed for this feature.

Functional capacity — use of the joints and ability to perform necessary duties or to work — does not necessarily parallel the degree of rheumatoid activity. Few patients whose rheumatoid process becomes inactive fail to acquire greatly enhanced function, unless severe and irreversible joint changes have occurred. Frequently, however, patients under treatment show increased joint function and capacity for work with little or no improvement in the chronic joint inflammation. In fact, some patients with severe rheumatoid polyarthritis continue to work despite pathologic changes and disability far greater than those of others who are incapacitated. The personal equation and many socioeconomic and psychologic factors determine these contradictory manifestations.

The ideal in the therapy of rheumatoid disease would be achieved by the complete arrest of pathologic activity and the physical, economic and social rehabilitation of the patient. Such a goal would often embrace two separate problems: the arrest of rheumatoid activity and the restoration of function or work capacity. The real effect of a specific therapeutic agent must be judged by its influence on the rheumatoid process. The increase of functional capacity cannot be attributed entirely to such a remedy unless the signs of rheumatoid activity are proportionately improved or abolished. This distinction is often overlooked in evaluating the results of a drug.

The enthusiastic atmosphere surrounding the institution of some new method of treatment often temporarily stimulates functional capacity without materially influencing the pathognomonic features of the disease. Increased locomotion effected by any means is naturally welcome but is not retained unless the underlying inflammation has simultaneously been suppressed. Functional capacity usually represents the effect of the whole therapeutic program, including many helpful measures not directly influencing rheumatoid activity, such as physical and occupational therapy, orthopedic aids, analgesics, and the psychologic forces, especially the patient-physician relation. In judging the result of any specific treatment or adjunct, one should therefore regard increased function as subsidiary to the progress of the characteristic signs, as in the score card.

Classification of Response

The chief purpose of the therapeutic score card is to arrive at total values that determine whether the patient is to be classified as apparently arrested, greatly improved, slightly improved or unimproved (or worse). After the patients are classified according to their scores, the results of scoring in each case are compared with an estimate previously made from knowledge of the patient and from the progress notes. From this comparison categories of response can be classified reliably according to the percentage

de on the score card The disease is apparently ested when the score totals 76 per cent or more, otal of 51 to 75 per cent indicates great improve- nt, 26 to 50 per cent slight improvement, and s than 25 per cent no improvement

Table 1 presents the score cards of 4 cases of umatoid arthritis, which are briefly described low The salient features of each case are easily

rheumatoid arthritis for 13 years On November 23, 1943, physical examination at the start of gold therapy revealed swelling of both wrists and the metacarpophalangeal and interphalangeal joints Both knees and ankles were involved, with much periarticular swelling, and there was limitation of joint motion, as well as tenderness and pain on motion A flexion deformity of the right hip joint was noted The erythrocyte sedimentation rate was 20 mm (Cutler method), and the hemoglobin 13.1 gm The patient weighed only 102 pounds and complained of severe pain and pain insomnia She was depressed and felt weak Her functional capacity

TABLE 1 *Therapeutic Score Cards of 4 Patients with Rheumatoid Arthritis*

noted by reference to the score card Patients representing each type of response are included to illustrate their classification in the various categories

CASE 1 (score-card status arrested) P H., a 52-year-old man, was seen with slowly progressing early rheumatoid arthritis of 8 months' duration On November 23, 1943, at the beginning of gold therapy, physical examination showed moderate swelling of the metacarpophalangeal joints of both hands, stiffness and tenderness at these joints and limitation of joint motion Cystic tendonitis, with tenderness, was also noted The average weight was 180 pounds, and there had been no weight loss There was a subjective complaint of moderate pain The patient was uncomfortable but stoical, he had been unable to work for the last 8 months The erythrocyte sedimentation rate was 8 mm (Cutler method), and the hemoglobin 90 per cent Gold therapy was completed on July 15, 1944

Examination on August 18, 1945 revealed no joint swelling, full joint motion and no pain or tenderness There was no change in weight, and full functional capacity was indicated by the fact that the patient had returned to work at his previous job The erythrocyte sedimentation rate was 7 mm (Cutler method), and the hemoglobin was 90 per cent.

CASE 2 (score-card status greatly improved) C C., a 49-year-old woman, had had active, moderately advanced rheumatoid arthritis with a fluctuant course for 12 years On November 23, 1943, at the beginning of gold therapy physical examination disclosed swelling of both wrists and metacarpophalangeal joints and of both knees There were limitation of joint motion and tenderness and severe pain on motion The patient who weighed 114 pounds, had lost weight, and her general physical condition was poor She was able to do only light housework The erythrocyte sedimentation rate was 23 mm (Cutler method), and the hemoglobin was 13.8 gm Gold therapy was completed on January 13, 1945

On August 3, 1945, joint swelling had decreased but slight swelling was present There was no limitation of joint motion or tenderness The erythrocyte sedimentation rate was 12 mm (Cutler method), and the hemoglobin was 14 gm The weight was 128 pounds The patient's general physical condition was excellent, and she was able to do full work

CASE 3 (score-card status slightly improved) C S., a 34-year-old woman, had had ambulatory, active, advanced

was limited to self-care Gold therapy was completed on January 13, 1945

On August 18, 1945, inflammatory joint swelling had decreased but was still present Joint motion had improved about 40 per cent, and joint tenderness had decreased about 40 per cent The erythrocyte sedimentation rate was 23 mm (Cutler method), and the hemoglobin 13.3 gm The patient had gained 28 pounds The pain was less severe, and she was able to sleep with less aspirin Her general outlook was better and she enjoyed food Functional capacity was limited to light work.

CASE 4 (score-card status unimproved) B H., a 58-year-old woman, had had active, early rheumatoid arthritis for 3 months On October 13, 1943, at the start of gold therapy, physical examination showed swelling of both wrists and metacarpophalangeal joints and swelling of both knees and ankles There was limitation of joint motion, as well as tenderness and pain on motion There had been no weight loss, the average weight being 152 pounds Pain was severe, with pain insomnia Her general physical condition was poor, and functional capacity was limited to light housework The erythrocyte sedimentation rate was 25 mm (Cutler method), and the hemoglobin 85 per cent Gold therapy was completed on October 28, 1944

On August 25, 1945 swelling of both wrists and metacarpophalangeal joints had decreased, as had the swelling of both knees There was no swelling of the ankles Limitation of joint motion and joint tenderness were unchanged The erythrocyte sedimentation rate was 25 mm (Cutler method), and the hemoglobin 13.5 gm The average weight was still essentially the same, and severe pain, with insomnia, was present General physical condition was still poor, and functional capacity was unchanged

OTHER FEATURES

Some characteristics of rheumatoid arthritis that are important in the diagnosis or progress of the patient have not been included among the features used for estimating response to therapy because they were not sufficiently informative for our purposes, or because they could only supply overlapping evidence already derived from other items in the score card

The signs that are especially typical of acute and subacute rheumatoid arthritis need no discussion, because our subject is chronic rheumatoid arthritis. A low-grade fever and tachycardia, which are sometimes noted in the course of active, chronic rheumatoid arthritis, are so characteristic of a florid rheumatoid process that they are usually accompanied by definite joint swelling as a more important guide to the patient's progress. In themselves these signs are not sufficiently specific for precise evaluation when they arise as prodromal symptoms of a flare-up in an apparently arrested patient. They merely signalize the probability of an impending relapse requiring close observation and treatment. The characteristic joint swelling of some degree ordinarily appears soon enough to serve as the chief guide to the response to treatment.

Muscle atrophy is usually a sign of advanced arthritis, either active or burnt out. The former process, in which muscle wasting and weakness are secondary manifestations of inflammation, disuse and trophic disturbances, is one of the late signs. Shrinking of muscle is often associated with, but does not give positive evidence of, rheumatoid activity, nor does the degree of atrophy parallel the severity of the activity with which it is allied. When the inflammation subsides, muscle wasting is likely to improve, partly or completely as a result of the abolition of pain, spasm and disability. The lag in muscle recovery, however, is apt to take so long after improvement or arrest of rheumatoid activity that it cannot serve as a practical index to therapeutic response.

Subcutaneous nodules, ganglions (tendon cysts), synovial swelling, nodular tendonitis and tenosynovitis are frequent manifestations of rheumatoid activity. They have not been tabulated in a special column, because they are usually associated with joint swelling and constitute a variation, or additional evidence, of soft-tissue inflammation. Such signs represent invasion of extra-articular, juxta-articular or periarticular structures by the rheumatoid process. Occasionally any of these pathologic changes precede definite joint swelling, persist after joint involvement is no longer discernible, or crop up when the clinical features appear to be improving. In many such cases these symptoms must be interpreted as evidence of rheumatoid activity equivalent to joint swelling and charted accordingly.

Roentgenologic changes offer definite aid in the diagnosis and in the grading of rheumatoid arthritis. When activity diminishes or subsides the x-ray pictures of the joints are slow to reflect the improvement in the articular structures for so long a period that they rarely give assistance in the evaluation of

response to therapy that is not adequately provided by clinical signs.

The demonstration of streptococcal agglutinin in the blood serum is regarded as strong evidence of activity.² The facilities for this test are limited to so few observers that it has been omitted from the score card.

There are other clinical findings, such as lymphadenopathy and splenomegaly, to mention only a few, that are not included. They are encountered too infrequently and their relation to the progress of these patients is too indefinite to warrant special consideration.

Of course, no mechanical scheme for rating the response of patients can be altogether perfect. The yardstick expounded recently by Bayles and Hall³ offers an excellent method of accurately assaying therapy. At times cases that completely defy accurate classification are encountered. According to our experience the number is likely to be small and negligible when a standardized method is employed in a large series of patients.

SUMMARY

The therapeutic score card provides a simple method of charting the effects of treatment on the main features of each patient's rheumatoid arthritis. The total progress, if any, can be summarized readily by the changes reflected in the chief characteristics of the clinical picture. This scheme affords a uniform method of assaying by definite standards a patient's initial condition and later course under therapy. The final classification into degrees of response provides a universally understandable and comparable set of criteria.

Reports based on some such method of scoring, even when derived by different observers, furnish a more consistent and easily correlated pool of information for the evaluation of therapeutic agents than is now available. The following benefits would accrue from the use of an accurately tabulated system embodying certain uniform standards and procedures: specific indexes of rheumatoid activity, assessment of the influence of treatment by the effect on such indexes, uniform rating of total results according to a sliding scale described, and use of an identical nomenclature for the various degrees of response.

CHIARI'S SYNDROME*

Report of a Case

HAROLD L. HIRSH, M.D.,† AND BENJAMIN MANCHESTER, M.D.‡

WASHINGTON, D. C.

CHIARI'S syndrome is a rarely observed clinical entity and is seldom diagnosed during life. It was first adequately described by Budd¹ in 1846 but bears the name of Chiari,² who in 1899 reported more completely 3 cases seen in his clinic and collected 7 additional cases. As first described the syndrome was a manifestation of a primary obliterating endophlebitis of the hepatic veins. Other related pathologic processes have subsequently been shown to produce this disease entity.

The symptom complex manifested by this syndrome is not generally known. A search of the literature reveals only about 70 reported cases. Out of 11,979 autopsies at the Stanford Department of Pathology since 1898, only 5 cases were found, an incidence of 0.42 per cent.³ At the Mayo Clinic, from 1910 to 1939, Kelsey and Comfort⁴ found 20 cases. The syndrome occurs in all ages and with equal frequency in both sexes. Over 50 per cent of the cases reported occurred in patients between the ages of twenty and forty-years,⁵⁻⁷ although the range was between seventeen months and seventy years.

The clinical picture of Chiari's syndrome, which is clearly illustrated by the following case report, is of special interest since the diagnosis was made before death.

CASE REPORT

R. B., a 24-year-old Negro, was admitted to Gallinger Municipal Hospital on December 24, 1943, complaining of increasing weakness, faintness and weight loss for the previous 6 months. During the period of his present illness he had consulted several physicians, and numerous nontoxic medications had been prescribed without avail. The patient admitted consuming about a quart of whiskey daily during the preceding 6 months. He had worked as a laborer first in a printing establishment and more recently in a steel mill. The remainder of the history was not remarkable except that he had eaten clay as a child. He denied any knowledge of venereal infection or treatment with any drugs known to him.

On admission the temperature was 100°F, the pulse 100, and respirations 28. The blood pressure was 130/80. In addition, marked pallor, dental caries and generalized lymphadenopathy were noted. The heart was not enlarged, and there were no thrills or shocks. The heart sounds were of good quality, with a regular rhythm, the aortic 2nd sound was greater than the pulmonic. A soft systolic murmur was audible over the precordium, loudest at the apex and not transmitted to the axilla. The lungs and abdomen were normal.

Laboratory studies revealed the presence of a marked normocytic, normochromic anemia, as demonstrated by a red-cell count of 1,500,000, with 3 gm of hemoglobin. The white-cell count was 2500, with 38 per cent lymphocytes, 30 per cent band neutrophils, 27 per cent segmented neutrophils, 4 per

*From the George Washington Medical Division, Gallinger Municipal Hospital, and the Department of Medicine, George Washington University School of Medicine.

†Clinical instructor in medicine, George Washington University School of Medicine.

‡Associate in medicine, George Washington University School of Medicine.

cent metamyelocytes and 12 per cent mononuclear cells. The platelet count was 146,000, the reticulocytes numbered 5 to 7 per cent. A Kahn test, a blood culture, the blood urea nitrogen, and urinalysis were normal. Twenty per cent sickling was noted in a 24-hour incubated specimen. The icterus index was 5.

The diagnosis was normocytic, normochromic anemia of unknown etiology.

A week after admission the patient manifested a painful swelling of the right leg that subsided during the following 2 weeks. During this time and for the next 2 weeks the temperature ranged between 100 and 103°F, and the pulse between 80 and 110. The physical findings remained essentially the same as on admission. The patient was given whole-blood transfusions, ferrous sulfate, vitamins and symptomatic measures, with improvement in the general condition and blood picture. The red-cell count rose to 2,550,000, with a hemoglobin of 7 gm, and the white-cell count to 5000, with 29 per cent lymphocytes, 2 per cent monocytes, eosinophils and basophils and 14 per cent band and 51 per cent segmented neutrophils. Meanwhile, studies were undertaken to ascertain the cause of the anemia. X-ray films of the chest, gastrointestinal tract, skull and long bones were entirely negative, as were regular and multiple precordial lead electrocardiograms. Examination of the stools for ova, parasites and blood was completely negative. Repeat blood cultures, blood urea nitrogen levels, various agglutination tests, icterus indexes, stool examinations and urinalyses continued to show no abnormality. The Frei skin test was negative. A first-strength tuberculin skin test was positive.

Two months after admission, a septic temperature developed. The patient appeared gravely ill and complained of abdominal pain, with generalized tenderness and distention. After a few days, he developed diarrhea, which showed no unusual bacteriologic findings but resisted all treatment. A week following the onset of these complaints he developed signs of thrombophlebitis of the left lower leg. Edema of the extremity advanced to involve the scrotum and penis and later the right lower leg. In the interim the liver became enlarged, ascites developed, and a distinct abdominal and thoracic venous pattern appeared. The venous pressure was markedly elevated in the lower extremities and normal in the upper extremities. The general condition became worse, examination of the blood revealed an anemia and leukopenia as severe as that on admission. The venous disease was treated symptomatically, and the previously described supportive measures were continued.

Two weeks after the development of thrombophlebitis chest pain, cough and hemoptysis, with no pulmonary signs, appeared. X-ray examination of the chest showed evidence of a small pulmonary infarct of the right upper lobe and thickened pleura at the right base. Other studies were repeated and were still within normal limits. In April, shortly after the pulmonary infarction, the patient began to improve. Examination of the blood showed a red-cell count of 2,800,000, with 8.5 gm of hemoglobin, and a white-cell count of 6200. Liver-function studies, including repeated hippuric acid synthesis, bromsulfalein and cephalin flocculation tests, were normal. Examination revealed evidences of thickened pleura at the right base, hepatomegaly (1 fingerbreadth below the costal margin) and minimal edema of the ankles. The last 2 months of hospitalization were relatively uneventful except for the development of a lymph-node abscess in the right axilla, which was incised and drained, and a bout of sickle-cell crises, with a decrease in the number of cells, a reticulocytosis of 11 per cent, slight jaundice and increased urobilinogen in the urine. These were minor incidents and apparently had no effect on the course. The patient was discharged on May 17, with diagnoses of thrombosis of the inferior vena cava, Chiari's syndrome and normocytic, normochromic anemia of undetermined etiology.

The patient was to be followed as an outpatient. He returned once for a check-up several weeks after discharge. The findings were unchanged. He was readmitted on June 29, 1944, complaining of fatigue, nervousness, weakness, pains in the wrists, fever and symptoms of an acute upper respiratory infection. Examination revealed a temperature of 102°F, a pulse of 110, an icteric tint to the scleras and skin, pallor, generalized lymphadenopathy, retinal hemorrhages, scattered rales in the left base, moderate cardiomegaly, a precordial (Grade I) blowing systolic murmur, hepatomegaly (1 fingerbreadth below the costal margin) and minimal ankle edema. Examination of the blood showed a red-cell count of 660,000, with 3 gm of hemoglobin, and a white-cell count of 3000, with 40 per cent lymphocytes, 6 per cent mononuclear cells and 7 per cent band and 47 per cent segmented neutrophils. Urinalysis and a Kahn test were negative. The patient was given transfusions and other supportive and symptomatic measures, but he continued to decline and died on the 5th hospital day with essentially no change in the findings. The terminal event was characteristic of a pulmonary infarct.

Autopsy Gross examination revealed a yellow tinge to the skin and scleras. Six hundred cubic centimeters of clear straw-colored fluid was present in the chest on the right and 1000 cc on the left, and 800 cc of fluid was found in the peritoneal cavity. In the pericardial sac there was 100 cc of similar fluid.

The liver was 4 cm below the costal margin. There were a few adhesions between the spleen and surrounding tissues. The liver was smooth, congested, swollen and extremely firm. On cut section there were marked congestion and an irregular yellowish area suggesting fatty degeneration. When the hepatic veins were opened partially organized clots, firmly adherent to the vessel wall, were found. On microscopic examination the liver showed tremendous destruction, hemorrhage and congestion. The bile ducts were dilated and filled with bile. There was thrombus formation in many veins, and periductal fibrosis was marked.

The right lung weighed 725 gm, with roughened pleura over the right upper lobe. The right upper lobe showed increased consistence, and a cavity 2 cm in diameter, surrounded by caseous material, was found in the substance of this lobe. A few calcified nodules were found in the right lower lobe, in addition to areas suggesting old infarcts. The left lung weighed 640 gm and showed areas of old and new infarcts in the lower lobe. Microscopic sections of the lungs revealed the alveoli filled with granular debris in which occasional ghostlike outlines of phagocytic cells were seen. Inflammatory cells surrounded the alveoli. Another section showed an organized thrombus, with fibroblastic proliferation in the surrounding tissues.

The heart weighed 380 gm. There appeared to be slight dilatation of the left ventricle. The endocardium was intact. Slight fibrosis and edema were noted on microscopic examination.

The spleen weighed 455 gm. The capsule was smooth and tense, except at the site of adhesions. On section, the pulp was deep pink, with a firm, almost rubbery consistence. There was a blurred appearance to the architecture. A few small, grayish-pink, round areas were present, suggestive of tuberculous nodules. The structural detail was lost in the infarcted area, which was surrounded by a zone of hyperemia, with diffuse reticular fibrosis. The malpighian nodules were less numerous and conglomerate than those usually seen.

The pancreas, gastrointestinal tract, aorta, adrenal glands and the genitourinary system, including the kidneys, prostate and bladder, were normal.

The inferior vena cava was thickened and narrowed. A dense, firm band formed most of the posterolateral wall. There were adherent patches in its upper portion. It was completely blocked about 2.5 cm below the renal vein where there was an organized, grayish-white, firm thrombus. Similar thrombi were found in the femoral veins. The azygos system was markedly dilated.

The anatomic diagnoses were thrombophlebitis of the hepatic veins, thrombosis of the inferior vena cava, lung abscess of the right upper lobe, multiple pulmonary infarcts, pleural and pericardial effusion and splenomegaly.

DISCUSSION

The case presented above is one of the few reported in which the diagnosis of Chiari's syndrome was

made during life. The development of abdominal pain, hepatomegaly, splenomegaly and ascites superimposed on peripheral edema as a result of peripheral thrombophlebitis made the diagnosis likely. This impression was confirmed at autopsy. This is a case of the chronic form of the syndrome in which prolonged survival was possible. The thrombosis was gradual, the occlusion was incomplete, and recanalization sufficient to allow for adequate collateral circulation and the re-establishment of biliary blood flow.

This syndrome may be due to primary disease of the hepatic venous system or secondary to disease in other parts of the body. Originally it was described as a primary endophlebitis of the veins of the liver.⁸ Simple thrombosis of the inferior vena cava above the entrance of the hepatic veins, with or without involvement of these veins, has also been shown to be responsible for this syndrome. Such thrombosis is frequent in the presence of inflammatory changes in the inferior vena cava,⁹⁻¹⁰ although Thompson and Turnbull¹¹ consider the inflammatory changes secondary to the thrombosis. The two processes are often associated and aid in the propagation of one another. It has been postulated that the entrance of the hepatic veins into the inferior vena cava provides a selective site for thrombosis because of the eddy currents formed at the oblique angle at which the hepatic veins empty into the vena cava.¹²⁻¹⁴ Torsion on the hepatic veins by the liver when in the upright position, causing mechanical damage and scar tissue occluding the veins, has been suggested as another mechanism favoring the production of thrombosis in the hepatic veins.¹⁵ Still another theory proposes that the venous thrombosis results from the retardation or even reversal of flow of venous blood at the diaphragmatic opening of the inferior vena cava as a result of increased intrathoracic pressure on inspiration. Several hypotheses favoring a congenital etiology have been advanced. Rosenblatt¹⁶ believed that the etiology could be fibrosis following a fetal interstitial hepatitis occluding the hepatic veins or preventing their union with the inferior vena cava. Moore¹⁷ suggested that there might be a patent ductus venosus that, as a result of some irritant, began to obliterate and extended to involve the hepatic veins. Another possibility is that the intrauterine process of obliterating many of the venae cavae progresses too far.¹⁸ A congenital stricture at the point of junction of the hepatic veins and inferior vena cava has also been suggested.¹⁹

Intrahepatic and extrahepatic causes have been described as causing thrombosis of the hepatic veins. Rolleston and McNee²⁰ believe that the condition is always secondary — it is frequently secondary to disease elsewhere in the body. Alcoholism,¹ syphilis,²¹ pregnancy¹¹ and chronic cough⁶ have been described as predisposing factors. Of the intrahepatic causes, tumors,^{3, 14, 22} cirrhosis,^{4, 18, 23-24}

umas,^{2, 4} hydatid cysts,^{5, 24} abscesses,^{4, 24} hepatitis^{16, 19} and perihepatitis²⁴ have been described. The mechanism responsible for thrombosis of the hepatic veins is thought to be due to pressure or injury to the veins, causing narrowing of the lumen and slowing of the circulation. Schüppel²⁵ was of the opinion that increased coagulability of the blood was necessary before thrombosis occurred. Many extra-hepatic causes have been reported: pancreatic cysts and enlarged peritoneal lymph nodes,²⁴ nonspecific inflammatory masses,²⁴ anomalies,^{6, 12} trauma,^{6, 15} scars,²⁰ acute or chronic constrictive pericarditis,^{11, 13} tumors,^{3, 4, 24} metastatic carcinomatous invasion or thrombosis of the inferior vena cava,^{3, 26} malignant or infectious emboli,²⁰ thrombophlebitis migrans,¹² local⁵ and general infection^{3, 13, 27, 28} and polycythemia rubra vera.^{25, 29-35}

The association of Chiari's syndrome and sickle-cell anemia in the case reported above aroused interest in the relation between the two diseases. A review of the literature failed to disclose a case of Chiari's syndrome secondary to sickle-cell anemia. It is well recognized that thrombotic episodes occur frequently in patients with this type of anemia, particularly while the patient is in a crisis. Although such episodes in this case did not occur during an exacerbation of the sickle-cell anemia, the development of widespread thrombosis in a patient with this disease is highly suggestive.

The clinical features of this syndrome vary, depending on whether the acute or chronic type is involved and on whether the occlusion is partial or complete and whether recanalization occurs. Hess⁶ in 1905 and Thompson and Turnbull¹⁴ in 1912 elaborated on the clinical aspects of the syndrome. The acute form, which results from a sudden obstruction of the outflow of hepatic venous blood, is manifested by abdominal pain, frequently over the liver and radiating to the back and shoulders, as well as by nausea and vomiting. On examination there is abdominal guarding, rapid, tender enlargement of the liver, splenomegaly on occasion and ascites. Sometimes the patient becomes delirious and comatose and finally goes into shock. Death invariably results in one to four weeks, unless the obstruction is incomplete or recanalization occurs. Jacobson and Goodpasture¹⁴ reported a case in which the patient developed sudden swelling of the liver and acidosis superimposed on signs of inferior vena cava obstruction, indicating occlusive involvement of the hepatic veins.

In the chronic form there is either gradual occlusion of the venous drainage of the biliary system or repeated thromboses in small vessels. The patient develops gastrointestinal symptoms consisting usually of indigestion, epigastric pain, nausea and vomiting. There is gradual enlargement of the liver, occasionally splenomegaly, ascites that reaccumulates rapidly and resists diuretics, a venous pattern on the abdomen and thorax, edema of the lower extremities

and, rarely, cyanosis and jaundice. Hoover¹³ reported a case in which findings did not appear until the occlusion was complete. Low-back pain attributed to congestion of the kidney has been reported as a prominent symptom.

It was postulated by Hutchison and Simpson¹³ that the ratio of collateral circulation to circulation lost by obstruction determines the severity of the symptoms and signs experienced by the patient. Collateral circulation occurs more frequently when the obstruction is gradual than otherwise. In the chronic form there is eventual development of delirium and coma as a result of liver failure. Death invariably occurs in six months, or at the most in several years^{23, 36} and is preceded by signs of liver failure, the hepatorenal syndrome³⁷ or renal failure.^{14, 24} Continued life is possible in limited thrombosis, incomplete occlusion, early recanalization or development of adequate collateral circulation. Hutchison and Simpson¹³ reported a case in which the patient lived for twenty-five years with manifestations of this syndrome, dying only as a result of a laparotomy. Other cases with prolonged survival in which autopsies were not done have been described.

Thompson and Turnbull¹⁴ observed that the collateral circulation on the thorax and abdomen developed more frequently in the chronic than in the acute form. Occasionally the liver is found to be small when the syndrome is secondary to cirrhosis. Hydrothorax with ascites has been reported.^{13, 24, 31} Albuminuria,¹² bilirubinuria,¹² bilirubinemia,¹² lowered plasma cholesterol,³⁸⁻⁴¹ absent cholesterol esters²⁴ and elevated blood urea nitrogen²⁴ are some of the abnormal laboratory findings infrequently found.

The syndrome must be differentiated from cirrhosis of the liver, acute hepatitis, thrombosis of the splenic veins, obstruction of the portal veins, constrictive pericarditis and acute pancreatitis. Abdominal pain—especially over the region of the liver—that sometimes radiates to the back and shoulders, enlargement of a smooth-edged liver and spleen, simultaneous rapid accumulation of ascites, resistance to diuretics, development of a collateral circulation and edema of the legs suggest Chiari's syndrome. The relatively short course of the disease, in addition to the absence of a nodular liver, jaundice, macrocytic anemia and spider angiomas, and normal liver-function studies differentiate the syndrome from portal cirrhosis. Peritoneoscopy also distinguishes the congested liver of Chiari's syndrome from the characteristic appearance in cirrhosis. Acute hepatitis is differentiated by the presence of jaundice, which is invariably absent in Chiari's syndrome, without rapidly accumulating ascites and peripheral edema, which are prominent in the cirrhosis.

Splenic-vein thrombosis is manifested by pain in the left upper quadrant, without tender enlargement

of the liver, ascites or peripheral edema. Obstruction of the portal vein is difficult to differentiate, except that there is rapid enlargement of the liver and formation of ascites with a caput medusae and dilatation of the veins of the abdominal wall. Jaundice, edema and anasarca are rare, and the condition is relatively benign, death being due to hemorrhage or intestinal infarction. Liver enlargement, jaundice and ascites are more marked in hepatic-vein than in portal-vein obstruction. In addition, there are usually leukopenia and anemia in Banti's syndrome.

Constrictive pericarditis is differentiated by a small heart, small pulse pressure, increased venous pressure in the upper as well as the lower extremities, paradoxical pulse, recurring ascites and edema of the lower extremities. Fluoroscopic, kymographic and electrocardiographic studies of the heart help to establish the diagnosis.

A primary tumor of the inferior vena cava may simulate the chronic form of Chiari's syndrome. These two conditions can sometimes be distinguished by the fact that the collateral circulation tends to flow caudad in hepatic vein obstruction and cephalad in inferior vena caval obstruction.

Acute pancreatitis is differentiated by the elevation of the serum amylase and lipase, and absence of a rapidly enlarging liver and symptoms of hepatic obstruction. In addition the shock in pancreatitis is usually out of proportion to the abdominal findings.

The onset of symptoms in the acute form of Chiari's syndrome has been mistakenly interpreted as indicating a surgical emergency of the abdomen.

The pathologic changes in the liver in the syndrome depend on whether the hepatic thrombosis is acute or chronic. In the acute variety the liver appears enlarged, smooth, purplish and highly congested. Wedge-shaped areas are seen if there is occlusion of single branches. The changes microscopically resemble an infarct of Zahn. The central veins are distended or thrombosed, the sinusoids are packed with erythrocytes, and a few inflammatory cells are observed. The central portion of the liver lobule is congested with hemorrhage. Later degeneration and necrosis of the liver cells in this area are seen. If the patient recovers, pseudocirrhosis supervenes. The liver is nutmeg in appearance, nodular and granular, with regeneration of cells and connective-tissue hyperplasia as parenchymal replacement. All degrees of congestion, central necrosis, atrophy and fibrosis are seen, with different stages in various parts of the liver. Compensatory hypertrophy of the uninvolved liver cells occurs. The changes in the chronic form resemble those of cardiac cirrhosis. Such changes have been produced experimentally in animals.⁴²⁻⁴⁷ Thrombosis of the hepatic veins produces portal hypertension and its resultant sequelae. Cirrhosis and primary car-

cinoma have been found superimposed in Chiari's syndrome in a significant number of cases. The relation is not understood, but it is suggestive that the presence of Chiari's syndrome predisposes to these lesions.

There are no known methods of treatment. Recovery or death depends on the rapidity of the obstruction of the hepatic venous drainage, the extent of the occlusion and the time required for canalization and the development of adequate circulation. Omentopexy resulted in death shortly after operation in several reported cases. Other operations to improve the circulation also terminated fatally.

SUMMARY

A case of Chiari's syndrome due to an endophlebitis of the hepatic veins complicating peripheral and inferior vena caval thrombophlebitis is reported. The diagnosis was made during life and confirmed at autopsy. The literature is reviewed, and the differential diagnosis of this syndrome is presented.

We are indebted to Dr. Roger Choisser and the members of the Pathology Department for permission to publish the autopsy findings on this case.

RECURRENT SPONTANEOUS EMPHYSEMA OF THE MEDIASTINUM WITH CONCOMITANT PNEUMOTHORAX*

Report of a Case

J D SCHENDSTOK, M D †

ARUBA, CURACAO

EMPHYSEMA of the mediastinum has several times been reported in the older literature as a finding in patients with chest injuries or at autopsy. Its occurrence, however, as a disease entity with characteristic clinical symptoms and possible spontaneous onset has been shown only recently by several authors, especially Hamman¹ in 1934. Since that time the publication of a number of clinical reports gives the impression that the condition is not extremely rare.²⁻⁴ A feature of clinical importance is the resemblance of some of the symptoms to those of coronary disease or myocardial infarction. The last fact may at the same time explain why the condition was apparently not recognized more frequently in the past.

The following case report serves as an illustration.

A 37-year-old American engineer was seen on December 22, 1942. The previous history was irrelevant except for three episodes of pain in the chest quoted from old records of the hospital, which are not discussed in detail since there was no definite proof that they were of the same nature as the symptoms described below.

On December 21 the patient had a tight feeling in the lower chest all day, which radiated to the left side of his neck. That evening, while he was sitting quietly in a chair, a rhythmic noise, apparently originating in the chest, struck his ear. The character of the noise was comparable to that of "water dropping on a shelf." The noise was loud enough to be noticed by his wife and by a visitor. One of the physicians of the hospital staff who was called stated that he could hear the sounds at 5 or 6 feet away from the patient's chest.

The patient was sent to the hospital the next morning for examination. He was still complaining about a tight feeling in the heart area but was not in acute distress. The pulse was 80 and slightly irregular and the respirations were normal, without dyspnea or cyanosis, the temperature was normal, and the blood pressure 100/70. Percussion of the heart and lungs revealed no abnormality except for an unusual amount of tympany over the heart area. There was a duplication of the 1st sound over all ostia but not with every heart beat. At that time no sounds could be heard except by stethoscope. A few extrasystoles were noted. No abdominal abnormality was observed, and the area of liver dullness was normal. The blood sedimentation rate (Westergren) was 8 mm in 60 minutes, and the white-cell count was normal.

Röntgenologic examination following ingestion of barium suspension in Trendelenburg's and other positions failed to show either a diverticulum of the esophagus or a hernia of abdominal viscera through the esophageal hiatus or other sections of the diaphragm. The patient's complaints subsided in a short time.

He experienced no similar difficulties until May 31, 1943. That night, without any known cause, he again experienced a dull pain in the cardiac and left infraclavicular areas, and he and his wife noticed rhythmic sounds audible at a distance from his chest. He was seen as an ambulatory patient several times, but was finally hospitalized on June 7 because he did not improve.

When examined on June 1 the patient was not in acute distress, but the pain was still present and was worse when he walked. He was not shortwinded. Physical findings were reported normal, except for an increase of voice and breath sounds on the left side.

On June 2 it was found that the 1st heart sound was preceded by a fine clicking sound "like rales", the 2nd sound was loud.

On June 5 the patient reported that he had heard the sounds in the chest again, especially associated with exercise, bending forward or getting up after lying down.

No new physical abnormalities developed during the 1st week after hospitalization. On June 1 examination of the blood showed a red-cell count of 4,020,000, with a hemoglobin of 84 per cent, and a white-cell count of 7550, with

*From the Hospital of the Lago Oil and Transport Company Limited
†Physician Lago Oil and Transport Company Limited

1 per cent band and 73 per cent segmented neutrophils, 24 per cent lymphocytes and 2 per cent monocytes. The sedimentation rate was 15 mm in 60 minutes, the fasting blood sugar was 97 mg, and the nonprotein nitrogen 27 mg per 100 cc. By June 7, the white-cell count had increased to 12,100, with 7 per cent band and 73 per cent segmented neutrophils and 20 per cent lymphocytes. The sedimentation rate was 15 mm in 60 minutes. Routine stool and urine examination were negative. On June 10, the white-cell count was 11,400 with 76 per cent segmented neutrophils, 21 per cent lymphocytes, and 3 per cent eosinophils.

By June 13 the patient was feeling better. He could still hear the sounds when lying on his left side supporting himself on his arm and fixing his chest in a certain phase between inspiration and expiration. With the stethoscope a peculiar knocking sound could be heard that was not rhythmic but was apparently synchronous with some of the heartbeats although skipping others.

Several x-ray films of the lungs were taken during this period of observation. An anteroposterior film taken on June 1 showed a few areas of calcification about the left hilus and in the right lower lobe, and a scar in the left apex. No evidence of air in the mediastinum could be demonstrated. Films of the chest taken on June 2 in the right oblique position again showed no air in the mediastinum but revealed a small, marginal left-sided pneumothorax.

The patient was discharged from the hospital on June 20, feeling completely normal. X-ray films of the chest in the anteroposterior and right oblique positions taken on January 19, 1945, for the purpose of follow-up failed to show any recent disease.

DISCUSSION

A comparison of the symptoms in the case presented above with those of several cases reported in the literature appears to justify the diagnosis of spontaneous mediastinal emphysema. A summary of the symptomatology in such cases follows.

Pain, which is a predominant feature, may be severe, moderate or, occasionally, entirely absent. In one of the few cases without pain a nocturnal coughing spell was the initial symptom.⁵ The pain is usually located over the precordium, less frequently laterally in the left chest and seldom in the right chest. Radiation seems to occur more frequently to the back or neck than to the left arm.³ The pain is often influenced by the position of the patient, increasing while he is lying on the left side.

True shock, dyspnea and cyanosis are not characteristic symptoms of this condition,³ although Miller⁶ reports dyspnea in his 4 cases. Marked changes of pulse rate and blood pressure are unusual. A slight elevation of the temperature is infrequently reported.

Inspection occasionally shows a decrease of expansion of the left side of the chest. A frequent and important sign is a tympanitic sound over the precordial area on percussion. A concomitant pneumothorax, often too small to cause any physical symptoms, need not be present to produce the condition.

Most characteristic are the auscultatory findings. The heartbeat may be audible without a stethoscope even at a considerable distance from the chest. This is due to the fact that the heart beats against air in the anterior mediastinum.⁷

With the stethoscope the sounds may be of a crunching, bubbling character,—like the noise

caused by the crumpling of cellophane,—“boiler like” or occasionally grating. They are usually systolic. The intensity of the sounds, like the pain, often increases when the patient turns on his left side.

Associated subcutaneous emphysema is an valuable aid in the diagnosis. It may be located in the neck or in the wall of the chest. The frequent concomitant pneumothorax is another way of escape of the air from the mediastinum.

Slight leukocytosis has occasionally been described.

Roentgenologically the air may be demonstrated in the mediastinum, often better in the oblique than in the anteroposterior view. The finding of a pneumothorax is easier and more frequently described than the demonstration of the air in the mediastinum itself. In view of the mechanism of development of this kind of pneumothorax it is likely that a late stage is represented, and that in the case reported above and similar cases the air had already moved from the mediastinum into the pleural cavity at the time of x-ray examination.

The prognosis in adults is apparently good. In the reports cited all patients recovered.

Most authors believe that spontaneous mediastinal emphysema is usually preceded by interstitial emphysema of the lungs. This condition is probably exceedingly frequent.

Small amounts of air in the pulmonary interstitium are probably resorbed. McGuire and Bean¹ make the following statement:

If a large amount of air escapes it may travel along the interstitial bands toward the hilum and enter the mediastinum. A second, and perhaps commoner pathway for the air to follow is to pass outward directly to the pleura along interstitial bands where it causes the formation of a bleb which may rupture and produce an ordinary pneumothorax. The air may go in both directions, producing both results.

Macklin⁹ inflated the bronchial tree of animals in experimental studies until the alveoli ruptured, and noticed that the air was usually transported to the hilus along the perivascular sheaths. Further inflation caused the air to collect in the mediastinum. Finally, the mediastinal wall ruptured and the air escaped into the pleural cavity.

A concomitant pneumothorax occurs frequently in cases of mediastinal emphysema. Macklin believes that it develops in the same way as in his experimental animals. It is remarkable that, so far, such pneumothorax has always been found on the left side.

SUMMARY

A case of recurrent spontaneous emphysema of the mediastinum, with concomitant pneumothorax, is reported, and the mechanism responsible for this condition is discussed.

UNILATERAL TREMOR OF THE LOWER EXTREMITY*

Its Association with Internal Derangement of the Ipsilateral Knee

LIEUTENANT COLONEL CHARLES J SUTRO, M C, A U S

ON orthopedic examination of 500 soldiers with recent or long-standing post-traumatic lesions of the knee, the existence of a bizarre type of intentional tremor involving the ipsilateral lower extremity was noted in 8. Most of these 500 soldiers had experienced pain in their knees in civilian life. Each of the 8 soldiers in question complained of recurrent swelling and pain of a single knee and weakness of the ipsilateral leg. Three of the 8 were not able actively to extend the affected leg to 180°, and this was first noted from three to ten years prior to entrance into the armed forces. The tremor was encountered when the involved leg was held in an actively extended attitude of 150° or more. Of further interest was the observation that the existence of this tremor was of more value than atrophy of the thigh in predicting the status of work efficiency of the quadriceps apparatus. Furthermore, the finding of a tremor of a single lower extremity as noted in this study suggested the possibility of a psychosomatic disturbance. On this basis, the test for the tremor provided a ready means to detect psychosomatic disorders in patients with derangement of the knees. It was believed that patients with such tremors were not suitable for elective orthopedic procedures without adequate psychiatric study. An investigation based on the examination of these 8 patients is presented.

PROCEDURE

The patient was seated on the examining table or chair in a position to permit active excursion of the lower extremities. The involved leg was actively extended to its maximal degree, while the opposite leg was held in a relaxed attitude at approximately 90° of flexion. When the test gave a positive reaction, a tremor involving the entire affected extremity, with repeated short excursions of the leg in flexion and extension, was noted from thirty to sixty seconds after the leg was extended to its maximal degree. This tremor, which caused a vertical oscillation of the extremity from one hundred to five hundred times a minute, without any pattern or fixed rhythm, lasted

uninterruptedly for ten minutes — the maximum period of observation. The tremor could be terminated quickly by actively or passively flexing the affected leg to an angle of approximately 90°. The height of the vertical oscillation as measured at the toes varied from 2.5 to 7.5 cm. The patients had no voluntary control over the rate or altitude of the tremor. Furthermore, the use of sedatives, such as phenobarbital and amytal in doses of 65 mg, produced no visible effect on the rapidity of the onset, rate or altitude of the oscillation of the leg. When the examiner percussed the flexed knee of the normal leg of the patient, a temporary increase in the rate and height of the tremor of the affected extended leg was noted. When both legs were simultaneously extended, the tremor was present only in the one with the involved knee (Fig 1). Infre-

FIGURE 1 Photograph of the Lower Extremities
Note that the right foot is out of focus because of the tremor

quently a very mild tremor of transitory nature was observed in the opposite uninvolved extended leg or upper extremities. In 4 of the 8 patients, hyperventilation became apparent four or five minutes after the onset of this test and was accompanied by severe pain in the affected limb. These tests for tremor were repeated each month during the period of two to fourteen months' observation.

*Knee injury incurred in line of duty

CLINICAL FINDINGS

Table 1 summarizes the clinical findings. A psychiatric examination revealed that 6 of the 8 patients exhibited general evidence of anxiety neurosis.

Only 1, who had had symptoms for ten years, was prior to these examinations that the involved extremity presented a tremor.

For patients with service-incurred injuries to articular cartilage of the femur developed a tremor of the affected limb after arthrotomy of the knee. They also showed definite physical findings frequently observed in states of anxiety. When 1 of these soldiers was placed in a branch of the service for which he expressed a specific preference, an excellent recovery was obtained. The tremor had completely disappeared within a year after the operation, although marked atrophy of the quadriceps muscles persisted. This soldier could only extend the leg of the affected limb against a considerable amount of resistance to the extensor apparatus. The other soldier was treated in the conditioning, orthopedic and psychiatric sections for a period of sixteen months without any amelioration in the status of the tremor of the limb. It was believed that the environment was a predisposing basis for many of his difficulties. He was, therefore, separated from the Army.

In the nonoperative group of 6, all but 1 of the soldiers were separated from the service. In spite of psychiatric, reconditioning and orthopedic treatment, no improvement was obtained either in the mental or in the physical reactions of these 5 soldiers. In the soldier in whom an excellent adjustment was made, re-examination a year later revealed an absence of the tremor of the affected leg, with a persistence of the atrophy of the quadriceps muscles. This soldier is performing regular duty in the armed forces.

DISCUSSION

One gains the impression that the tremor demonstrated in these 8 cases was similar to that noted in hands affected with writer's cramps or fatigue neurosis. In parallel investigations, a similar tremor was temporarily produced in lower extremities that had recently been immobilized in plaster of Paris bandages for three or more months for treatment of a fractured leg. With exercises and training, the tremor disappeared rapidly in the patients who did not present any tendency toward an anxiety state. From the observations made in these studies, it was suspected that a psychosomatic disturbance had considerable influence on the production and extent of duration of this tremor. For that reason arthrotomy, when indicated, was postponed until a complete psychiatric study had been made. Most soldiers with derangement of the knees who had such

tremors were separated from the service without surgical intervention, since it was almost impossible to obtain a complete mental and physical recovery in the military environment. A change to civilian life was therefore suggested as part of the preoperative and postoperative care of such patients.

Undoubtedly the same sequence of events occurs in persons whose knees are injured in industrial or other accidents, and the identical method of handling such cases appears indicated. The tremor must be differentiated from that caused by malingering, Parkinson's disease or Wilson's disease.¹⁻⁹

SUMMARY

In a group of 500 soldiers with lesions affecting the knee, in 8 there was a coarse tremor limited to the ipsilateral lower extremity that was brought out by active extension of the leg. Six of these patients so affected presented evidence of anxiety states. In 2 of the 8 soldiers the tremor developed after arthrotomy of the knee was performed. Only 1 of the 2 made a complete recovery after vocational readjustment. The other was separated from the service because of aggravation of the tremor. In the nonoperative group of 6, only 1 patient made a recovery after vocational readjustment. The other 5 were separated from the service because the environment was considered to have a decided influence on the persistence of the tremor and symptoms.

The finding of such a tremor in association with lesions of the knee suggests the existence of an anxiety neurosis. When noted, especially in connection with an industrial or other accident or in a member of the armed forces, arthrotomy of the knee should be postponed or avoided until complete psychiatric examination and treatment are pursued. Change in environment, such as separation from the service, is recommended as part of the treatment.

Examination to determine the presence or absence of such tremor is suggested as a routine measure in patients with derangement of the knee joint.

MEDICAL PROGRESS

PRESENT CONCEPTS OF BENIGN BREAST DISEASE*

IRA T. NATHANSON, M.D.†

BOSTON

ADVANCES in knowledge of factors concerned in mammary development and function have considerably changed concepts of breast disease in human patients. Through information resulting from systematic surveys, histories, examinations and experimental studies, a new approach to the problem has become available. Since it was demonstrated that hormones were involved in the physiologic response of the breast, it became obvious that they might be of major importance in the genesis of diseases of the mammary gland. Thus, a comprehension of the histology and physiology of the gland is essential to a better understanding of factors that are of possible significance in the initiation of benign and malignant breast lesions. Reviews of the endocrine physiology of the breast have appeared elsewhere,¹⁻³ so that the following discussion is limited to the more pertinent studies. It should be pointed out that much of the present knowledge of the breast is based on animal experimentation, such data are of extreme value, but as has previously been pointed out, caution in the interpretation as applied to human material is necessary.⁴ It is the purpose of this paper to evaluate the available information and to indicate present trends of thought regarding breast disease in human beings.

PHYSIOLOGIC CHANGES

The mammary gland must be considered a part of the female reproductive system and, as such, subject to the same stimuli throughout life as the other organs of reproduction. Changes in the breast seem to be directly related to those occurring in the uterus during the various phases of pituitary and ovarian activity and during pregnancy. Using this concept as a basis, one may review with greater clarity the changes at various periods of life.

At Birth

Activity of the mammary ducts in newborn infants of both sexes is frequent. In addition, mammary enlargement (mastitis neonatorum) and secretion (witch's milk) may occur. These changes originate from endocrine stimuli of maternal origin, since cessation of function and regression of the active processes in the breast follow shortly after delivery.

*From the Medical Laboratories of the Collis P. Huntington Memorial Hospital and the Tumor Clinic of the Massachusetts General Hospital, Boston, and the Pondville Hospital (Massachusetts Department of Public Health), Walpole, Massachusetts.

This is publication No. 620 of the Harvard Cancer Commission and No. 116 of the Pondville Hospital.

†Associate in surgery, Harvard Medical School; assistant surgeon, Massachusetts General Hospital and Pondville Hospital.

At Puberty

After birth the breasts are inactive until the appearance of changes leading to puberty. In the female, development of the breast, which usually begins at about the tenth year, is associated with a definite increase in the activity of the gonads.⁴ At first the changes are confined to the ducts and periductal connective tissue, but even before the menarche there is evidence of acinar and lobule formation. Changes may also be noted in the male breast between the ages of twelve and seventeen.⁴ The histologic picture is similar to that observed at the onset of breast growth in the female. These changes usually subside spontaneously in contrast to those in the female, in which mammary development usually continues once the cyclic activity of the menses is established.

In Cyclic Women

There is convincing evidence that cyclic change occurs in the breast that can be correlated with rise and fall in ovarian activity during the menstrual cycle.⁷⁻¹² Whether these changes are purely epithelial, vascular, secretory or combinations of these is a matter of dispute. Such divergencies of opinion are understandable when it is recognized that studies of whole sections of the breast showed that the degree of activity is not similar throughout.¹¹ This has been attributed to the lack of a uniform response to a given stimulus, that is tissue sensitivity and, as pointed out below, may be a determining factor in certain types of breast disease. Moreover, many of the studies were made on small areas of breast tissue removed coincidentally with localized pathologic processes and therefore should not be considered typical of the normal breast. Review of breast tissue removed from patients dying from various causes is subject to the criticism that the structures may have been altered as a result of the primary disease. Thus, it is apparent that no concrete concept of the changes can be complete until whole sections are made from many normal breasts throughout the menstrual cycle. This is a difficult task, but Foote and Stewart¹² have made an excellent attempt to study such changes from material obtained from apparently healthy women who died accidentally. They were able to predict, with a high percentage of success, the stage of the menstrual cycle from a study of the breast tissue. Since cyclic changes in the endometrium are well recognized and the stage of the menstrual cycle can be determined with con-

erable accuracy from the endometrial pattern, they utilized this technic as a control. They further found that the status of the breast — particularly the lobule — in post-mortem material was vastly different from that in surgical specimens.

Complete development of the breast is manifested by the presence of certain static structures (ducts, lobules and acini). Variations of these structures may occur during the menstrual cycle as a result of rhythmic stimulation with the hormones. The breast is prepared each month for pregnancy, since it is subject to the same influence as the uterus.³ Like the uterus it has both a proliferative phase induced by estrogens and a secretory phase effected by progesterin and the anterior lobe of the pituitary gland. A process analogous to menstruation then occurs and is represented by an involutional change and absorption of the secretion if pregnancy does not ensue. It is only by accepting these possibilities that one may have a concise and logical explanation for the hormonal and nervous action on the breast with the resultant changes during catamenia, pregnancy, lactation and the pathologic states described below.

In Pregnancy and Lactation

Changes during pregnancy and lactation are well recognized and are certainly controlled to a large extent by hormonal secretion. The alterations in the breast in the first half of pregnancy are rapid growth of the lobules and epithelial proliferation, in the latter half the acinar epithelium enlarges and secretes and thus causes distention of the acini.² During pregnancy the placenta is probably the main source of stimulation, whereas during lactation the pituitary gland is the likeliest dominant activator of mammary function.

At the Climacteric

At the menopause, when ovarian stimuli recede to a low ebb, the mammary gland exhibits regressive changes. In some cases evidence of activity in the breast is apparent years after the cessation of the menses. Such activity may be caused by continued but lowered secretion of an activating hormone, possibly from the ovary. In other cases, particularly late in life, there may be an almost complete atrophy of the gland.

In summary, it may be stated that mammary development, growth and regressive changes depend on the rise and fall of hormonal stimuli principally from the gonads and the hypophysis. The exact mechanism by which the metamorphosis takes place is not fully understood. Present knowledge, however, allows at least a working hypothesis for the understanding of some of the diseases of the breast described below.

The Nervous System

Evidence exists that the nervous system is involved in some fashion in the physiologic responses

of the breast. Suckling in the virgin rat resulted in mammary development, lactation and inhibition of the estrous cycle.¹⁵ This presumably works reflexly by way of the hypophysis. In women, suckling certainly plays an important role in the maintenance of lactation. Moreover, numerous cases are cited of lactation and breast changes in children, the virgin female and even in the male after stimulation of the nipple alone.¹⁴ Many lesions of the breast are associated with disease in the pelvis that affects the breast not only by disturbance of ovarian function but also by way of the pelvic sympathetic nerves.¹¹ It must be inferred therefore that the nervous system is important for the maintenance of mammary function, but probably in an indirect manner since the elaboration of hormones may be partially initiated by or dependent upon nervous stimuli.

PRECOCIOUS DEVELOPMENT (INFANTILE HYPERTROPHY)

Aside from the changes noted at birth there are numerous cases of premature mammary development in children. These are usually associated with demonstrable lesions, although in some cases the etiology is vague.

Lesions of the third ventricle. Tumors, defects and inflammatory lesions in the region of the third ventricle give rise to true pubertas praecox. The breast changes are merely part of the general picture of developmental and sexual advance. The most probable explanation for the effect is a stimulation of the hypophysis via the hypothalamus and infundibulum. The breasts exhibit ductal development but rarely lobule formation. Ovaries of these patients show marked follicle development and cyst formation, and in 1 case a true corpus luteum was reported suggesting stimulation by the hypophysis.¹⁶ This activity in the ovary probably initiates the secretion of the hormones, which in turn causes growth of the secondary sex organs, including the breast. This thesis is confirmed by assays of the urine of these patients, which usually show increased levels of gonadotropic hormone, estrogens and 17-ketosteroids (androgens).¹⁷

Lesions of the adrenal cortex. In general, neoplasms or hyperplasias of the adrenal cortex in the female child produce masculinization, but there are cases in which the first signs are feminization.¹⁸ Because the adrenal glands are a probable source of estrogens it is possible to explain the early mammary hypertrophy on this basis, especially since excretion studies reveal increased amounts of the hormone.¹⁶ When masculinization and regression of the breast occur they are accompanied by a significant increase in the androgenic output, even though the estrogen levels usually remain elevated. Thus, it is reasonable to assume that this reversal is of androgenic origin and therefore that the androgens

are not responsible for the original breast hypertrophy

Ovarian lesions Among the associated exciting factors of premature mammary development are lesions such as the granulosa-cell tumor and teratoma of the ovary. These lesions, when active, are usually associated with generalized feminization, breast enlargement, uterine bleeding and cornification of the vaginal epithelium. This syndrome must be distinguished from true pubertas praecox. As in the other states, however, the breast changes are probably produced by estrogens elaborated by the tumors, since the cells involved presumably secrete the hormone. Assays of the urine in most cases reveal elevated excretion levels of estrogens, whereas the titers of the other hormones remain normal.¹⁶

Idiopathic breast development In some children premature breast development occurs without known cause. The process may be transient or may persist. Other secondary sex changes are usually normal or only slightly advanced. Histologic examination reveals ductal development, but for the most part assays of the urine for hormones do not reveal any abnormalities. In the syndrome of osteitis fibrosa disseminata, breast enlargement is a part of the associated sexual precocity.¹⁹

Hormone-induced infantile hypertrophy It has been the experience of many that administration of estrogenic hormone to the female child for gonorrheal vaginitis frequently results in mammary growth. There is no question that these changes are due to the hormone, since regression occurs rather rapidly after cessation of treatment.

In summary, the available evidence suggests that premature mammary development is due in large part to hormonal stimulation. Histologically the changes are confined for the most part to the duct system and periductal connective tissue. Thus, they correspond to a state produced by a known stimulus (estrogens) and in this sense represent a physiologic response to premature or excess secretion of the hormones, as a result of endocrine disturbances. Removal of such a stimulus is followed by a rapid regression to the normal state. Of significance is the fact that precocious development of the breast may be an indication of a pathologic state elsewhere, and as such may be a valuable aid in diagnosis.

HYPERTROPHY

Asymmetrical prepubertal hypertrophy At about the age of ten, when normal breast development usually begins, there may be a rapid growth of one breast that is out of proportion to that of the other. This is often referred to as "early ripening" and is not true hypertrophy. Eventually the more slowly developing breast usually attains the size of the larger breast, and at the time of puberty both are of almost equal size and within normal limits. Since

in most females the breasts are not identical in size, this seems to represent an exaggeration of a normal phenomenon. Histologically the changes are no different from those in the normal adolescent. Estrogen excretion is usually normal. The early inequality is explained by some investigators as an increased sensitivity of the involved organ to a normal physiologic stimulus.

Pubertal and postpubertal hypertrophy Pubertal and postpubertal hypertrophic abnormalities may be classed as true hypertrophy. The process is either unilateral or bilateral and is easily distinguished from early ripening by the size of the breast. It may first manifest itself at puberty, although similar changes are associated with pregnancy and lactation. Histologically there is an increase in ductal growth, but connective-tissue increase is more striking. Lobular development is rare especially in the virginal type. Estrogen assays are usually normal but may show elevated levels of the hormone. Again, as in early ripening, the changes may be due to an excessive stimulation or to increased sensitivity of the breast involved.

FIBROADENOMA

Fibroadenomas of the breast are the most frequent tumors in young women, the majority appearing between the second and third decades. The lesions are generally slowly growing and although not noticed may arise in the early years after the menarche when atypical menstrual activity is not unusual. They resemble the changes seen in early ripening and hypertrophy. They are rare before puberty and after the menopause, except possibly in the presence of a granulosa-cell tumor of the ovary. It has been suggested that the greatest incidence of the tumor is in women of a definite constitutional type — nulliparous women with a relative underdevelopment of the pelvic organs and breast.²⁰ Fibroadenomas are also found, however, in association with hypertrophy of the breast in a small percentage of cases. Changes have been observed in the size and histologic appearance of these tumors during the menstrual cycle,¹⁸ pregnancy and lactation.^{21, 22}

Fibroadenomas are distinctly different from other lesions of the breast, in that they may respond to a stimulus in the same fashion as normal breast tissue. It has therefore been suggested that they are not true tumors but merely a localized response to a normal stimulus as a result of a specific tissue sensitivity, such a response is akin to the grosser manifestations of early ripening and asymmetrical hypertrophy. This thesis is enhanced by the fact that the lesions may be multiple and may continue to appear as mammary development progresses. In addition, areas resembling fibroadenomas may be found in a breast without actual formation of a mass. Observation suggests that these lesions are of hormonal origin. It is possible that they arise as a result of abnormal or excessive stimulation, since they usually

when the metabolism and secretion of the sex hormones are at their height and may be abnormal. It is difficult to explain why circulating hormones do not affect the breast tissue in a uniform manner, but as stated above, present evidence suggests that such lack of uniformity exists and probably depends on individual susceptibility.^{10, 23}

CHRONIC CYSTIC MASTITIS

pointed out frequently in the last few years, clinicians and pathologists often use this terminology as a catchall for a variety of benign lesions without tumor formation. It is now recognized that some of the lesions included under the diagnosis of chronic cystic mastitis can be distinguished as distinct entities and should be so designated. I am in accord with this point of view and plead for the term chronic cystic mastitis be discarded. It is essential that a working classification based on clinical and microscopic evidence be established in investigation of possible causative factors and natural history of any specific lesion. A number of writers have attempted to establish such a classification, but because of variations in interpretation of nomenclature, confusion exists even among those who have made special efforts to study the problem, owing partly to the difficulty in observing the process as it develops and partly to the variety of changes that coexist in the same breast. At any rate, the situation is being clarified, and it is likely that agreement among the various workers will be forthcoming as more material is studied and correlated. The importance of unanimity of opinion lies in the fact that some lesions included in the diagnosis of chronic cystic mastitis may lead to cancer, whereas others may be of no significance. Discussions dealing with this subject should be reviewed and evaluated by the interested reader.^{2, 13, 14, 24-30} It is not within the realm of this review to attempt a continuation of apparently contradictory viewpoints. Nevertheless a description of clinical syndromes frequently seen is indicated, to stimulate further investigation and clarification.

A syndrome in which the earlier signs are characterized by premenstrual swelling and pain associated with tenderness on palpation seems to be a distinct entity. The relief following the onset of the menses is dramatic. It is recognized that similar symptoms may be present in apparently normal women and, as has been stressed, may be an integral part of the normal breast cycle in preparation for pregnancy. The patients seen by the physician, however, usually have an aberration of an apparently normal process. The early physical signs are usually minimal and, besides slight premenstrual swelling and venous engorgement, may reveal only a slight thickening in the upper outer quadrant. Histologically there may be only a slight increase in the periacinar connective tissue and edema. As the process continues the symptoms and signs be-

come more prominent. There may be only an accentuation of nodularity in the upper outer quadrant, but usually the process is more extensive. There may be an increase in the density of the breast, which is well differentiated from the overlying skin, the subcutaneous tissue and the underlying structures. In the advanced stages the entire breast resembles a saucer or disk, and a definite edge can be palpated. The gland may be finely granular or nodular and in the premenstruum exhibits marked swelling and venous dilatation that may account for the cyclic pain. On microscopic examination there is usually a marked increase in the connective tissue stroma, with loss of or defective lobule formation. Frequently, in addition, there is proliferation of the acini, although the epithelium itself is not hyperplastic. Many variations of the process are seen. These lesions usually occur in the second and third decades of life in women who have not been pregnant. The process resembles both clinically and histologically the localized fibroadenoma. Menstrual cycles may be of shorter intervals than usual, accompanied by a scant flow of short duration. The incidence of sterility is high, and in women who have borne children the lesion is sometimes seen after a long period of infertility. Terms suggested for such processes are "adenofibrosis,"²⁴ "lobule alteration"¹³ and "fibroadenomatosis."²⁵ The secretions of the ovaries seem to be a prerequisite for the production of this syndrome, although they may not be the exciting factors. Nervous stimuli, vascular reaction and the mechanisms of hormonal secretion are closely interwoven, so that all three factors may be involved in the process, particularly regarding the edema and congestion. Excretion studies are slightly suggestive of a hormonal imbalance. The possible role of unopposed or atypical stimulation by the hormones also remains to be clarified. Slight abnormalities in the menstrual cycle and associated pelvic disease suggest a hormonal etiology. It can be concluded that, as in fibroadenoma, the hormones are involved but that other factors are necessary for the production of the syndrome.

Another lesion is characterized by discharge from the nipple. The process is sometimes associated with swelling and cyclic or acyclic pain. The discharge may abate at the menses, but generally persists throughout the cycle. It may be serous or may resemble colostrum and show varying degrees of viscosity. It is to be distinguished from the serosanguinous or sanguinous discharge frequently associated with duct papillomas, marked epithelial hyperplasias and carcinoma. Examination usually reveals dilatation of the ducts that is sometimes segmental and simulates cysts, especially near the areola. The dilated ducts can usually be palpated as cordlike structures radiating from the nipple. Slight nodularity may be found elsewhere in the breast. The nipples are frequently crusted, the mammary tissue itself is ill defined, and the breast

are not responsible for the original breast hypertrophy

Ovarian lesions Among the associated exciting factors of premature mammary development are lesions such as the granulosa-cell tumor and teratoma of the ovary. These lesions, when active, are usually associated with generalized feminization, breast enlargement, uterine bleeding and cornification of the vaginal epithelium. This syndrome must be distinguished from true pubertas praecox. As in the other states, however, the breast changes are probably produced by estrogens elaborated by the tumors, since the cells involved presumably secrete the hormone. Assays of the urine in most cases reveal elevated excretion levels of estrogens, whereas the titers of the other hormones remain normal.¹⁶

Idiopathic breast development In some children premature breast development occurs without known cause. The process may be transient or may persist. Other secondary sex changes are usually normal or only slightly advanced. Histologic examination reveals ductal development, but for the most part assays of the urine for hormones do not reveal any abnormalities. In the syndrome of osteitis fibrosa disseminata, breast enlargement is a part of the associated sexual precocity.¹⁹

Hormone-induced infantile hypertrophy It has been the experience of many that administration of estrogenic hormone to the female child for gonorrheal vaginitis frequently results in mammary growth. There is no question that these changes are due to the hormone, since regression occurs rather rapidly after cessation of treatment.

In summary, the available evidence suggests that premature mammary development is due in large part to hormonal stimulation. Histologically the changes are confined for the most part to the duct system and periductal connective tissue. Thus, they correspond to a state produced by a known stimulus (estrogens) and in this sense represent a physiologic response to premature or excess secretion of the hormones, as a result of endocrine disturbances. Removal of such a stimulus is followed by a rapid regression to the normal state. Of significance is the fact that precocious development of the breast may be an indication of a pathologic state elsewhere, and as such may be a valuable aid in diagnosis.

HYPERTROPHY

Asymmetrical prepubertal hypertrophy At about the age of ten, when normal breast development usually begins, there may be a rapid growth of one breast that is out of proportion to that of the other. This is often referred to as "early ripening" and is not true hypertrophy. Eventually the more slowly developing breast usually attains the size of the larger breast, and at the time of puberty both are of almost equal size and within normal limits. Since

in most females the breasts are not identical in size, this seems to represent an exaggeration of a normal phenomenon. Histologically the changes are no different from those in the normal adolescent. Estrogen excretion is usually normal. The early inequality is explained by some investigators as an increased sensitivity of the involved organ to a normal physiologic stimulus.

Pubertal and postpubertal hypertrophy Pubertal and postpubertal hypertrophic abnormalities may be classed as true hypertrophy. The process is either unilateral or bilateral and is easily distinguished from early ripening by the size of the breast. It may first manifest itself at puberty, although similar changes are associated with pregnancy and lactation. Histologically there is an increase in ductal growth, but connective-tissue increase is more striking. Lobular development is rare especially in the virginal type. Estrogen assays are usually normal but may show elevated levels of the hormone. Again, as in early ripening, the changes may be due to an excessive stimulation or to increased sensitivity of the breast involved.

FIBROADENOMA

Fibroadenomas of the breast are the most frequent tumors in young women, the majority appearing between the second and third decades. The lesions are generally slowly growing and although not noticed may arise in the early years after the menarche, when atypical menstrual activity is not unusual, they resemble the changes seen in early ripening and hypertrophy. They are rare before puberty and after the menopause, except possibly in the presence of a granulosa-cell tumor of the ovary. It has been suggested that the greatest incidence of the tumor is in women of a definite constitutional type — nulliparous women with a relative underdevelopment of the pelvic organs and breast.²⁰ Fibroadenomas are also found, however, in association with hypertrophy of the breast in a small percentage of cases. Changes have been observed in the size and histologic appearance of these tumors during the menstrual cycle,¹⁰ pregnancy and lactation.^{21, 22}

Fibroadenomas are distinctly different from other lesions of the breast, in that they may respond to a stimulus in the same fashion as normal breast tissue. It has therefore been suggested that they are not true tumors but merely a localized response to a normal stimulus as a result of a specific tissue sensitivity, such a response is akin to the grosser manifestations of early ripening and asymmetrical hypertrophy. This thesis is enhanced by the fact that the lesions may be multiple and may continue to appear as mammary development progresses. In addition, areas resembling fibroadenomas may be found in a breast without actual formation of a mass. Observation suggests that these lesions are of hormonal origin. It is possible that they arise as a result of abnormal or excessive stimulation, since they usually

cur when the metabolism and secretion of the sex hormones are at their height and may be abnormal as well. It is difficult to explain why circulating hormones do not affect the breast tissue in a uniform manner, but as stated above, present evidence suggests that such lack of uniformity exists and probably depends on individual susceptibility.¹⁰⁻²³

CHRONIC CYSTIC MASTITIS

As pointed out frequently in the last few years, both clinicians and pathologists often use this terminology as a catchall for a variety of benign lesions without tumor formation. It is now recognized that some of the lesions included under the diagnosis of chronic cystic mastitis can be distinguished as definite entities and should be so designated. I am fully in accord with this point of view and plead that the term chronic cystic mastitis be discarded. It is essential that a working classification based on clinical and microscopic evidence be established for an investigation of possible causative factors and a natural history of any specific lesion. A number of writers have attempted to establish such a classification, but because of variations in interpretation of nomenclature, confusion exists even among those who have made special efforts to study the problem, owing partly to the difficulty in observing the process as it develops and partly to the variety of stages that coexist in the same breast. At any rate, the situation is being clarified, and it is likely that agreement among the various workers will be forthcoming as more material is studied and correlated. The importance of unanimity of opinion lies in the fact that some lesions included in the diagnosis of chronic cystic mastitis may lead to cancer, whereas others may be of no significance. Discussions dealing with this subject should be reviewed and evaluated by the interested reader.¹³⁻¹⁴⁻²⁴⁻³⁰ It is not within the realm of this review to attempt a classification of apparently contradictory viewpoints. Nevertheless a description of clinical syndromes frequently seen is indicated, to stimulate further investigation and clarification.

A syndrome in which the earlier signs are characterized by premenstrual swelling and pain associated with tenderness on palpation seems to be a distinct entity. The relief following the onset of the menses is dramatic. It is recognized that similar symptoms may be present in apparently normal women and, as has been stressed, may be an integral part of the normal breast cycle in preparation for pregnancy. The patients seen by the physician, however, usually have an aberration of an apparently normal process. The early physical signs are usually minimal and, besides slight premenstrual swelling and venous engorgement, may reveal only a slight thickening in the upper outer quadrant. Histologically there may be only a slight increase in the periacinar connective tissue and edema. As the process continues the symptoms and signs be-

come more prominent. There may be only an accentuation of nodularity in the upper outer quadrant, but usually the process is more extensive. There may be an increase in the density of the breast, which is well differentiated from the overlying skin, the subcutaneous tissue and the underlying structures. In the advanced stages the entire breast resembles a saucer or disk, and a definite edge can be palpated. The gland may be finely granular or nodular and in the premenstruum exhibits marked swelling and venous dilatation that may account for the cyclic pain. On microscopic examination there is usually a marked increase in the connective stroma, with loss of or defective lobule formation. Frequently, in addition, there is proliferation of the acini, although the epithelium itself is not hyperplastic. Many variations of the process are seen. These lesions usually occur in the second and third decades of life in women who have not been pregnant. The process resembles both clinically and histologically the localized fibroadenoma. Menstrual cycles may be of shorter intervals than usual, accompanied by a scant flow of short duration. The incidence of sterility is high, and in women who have borne children the lesion is sometimes seen after a long period of infertility. Terms suggested for such processes are "adenofibrosis,"²⁴ "lobule alteration"¹³ and "fibroadenomatosis."²⁵ The secretions of the ovaries seem to be a prerequisite for the production of this syndrome, although they may not be the exciting factors. Nervous stimuli, vascular reaction and the mechanisms of hormonal secretion are closely interwoven, so that all three factors may be involved in the process, particularly regarding the edema and congestion. Excretion studies are slightly suggestive of a hormonal unbalance. The possible role of unopposed or atypical stimulation by the hormones also remains to be clarified. Slight abnormalities in the menstrual cycle and associated pelvic disease suggest a hormonal etiology. It can be concluded that, as in fibroadenoma, the hormones are involved but that other factors are necessary for the production of the syndrome.

Another lesion is characterized by discharge from the nipple. The process is sometimes associated with swelling and cyclic or acyclic pain. The discharge may abate at the menses, but generally persists throughout the cycle. It may be serous or may resemble colostrum and show varying degrees of viscosity. It is to be distinguished from the serosanguinous or sanguinous discharge frequently associated with duct papillomas, marked epithelial hyperplasias and carcinoma. Examination usually reveals dilatation of the ducts that is sometimes segmental and simulates cysts, especially near the areola. The dilated ducts can usually be palpated as cordlike structures radiating from the nipple. Slight nodularity may be found elsewhere in the breast. The nipples are frequently crusted, the mammary tissue itself is ill defined, and the breast

is lax. If secretion is not obvious, removal of the crust, with gentle pressure on the breast, usually results in the escape of fluid from the nipple. On gross and microscopic examination the ducts are dilated and contain secretion, desquamated cells and debris. Cheesy, inspissated material and segmental dilatations, which appear cystic, are often seen. Hyperplasia of the duct and acinar epithelium may be superimposed. A sequel of duct stasis and dilatation may be erosion of the epithelial lining.¹³ If the surrounding stroma is fatty, a reaction as manifested by fat necrosis may be seen. These lesions occur most frequently during the third and fourth decades of life. Many cases appear at onset of the menopause. Remission of symptoms and signs is frequent after castration or when the menopause is complete. The menstrual cycles may be normal, but prolongation of the interval is not unusual. In contrast to the findings in adenofibrosis, the endometrium is often atypical. Absence of the secretory phase is a frequent finding, although hyperplasia is relatively rare.³ Many women with this disease have borne children. Lactation may be normal, but faulty lactation or premature weaning precedes the onset of the disease in many cases. Pelvic disease occurs fairly often in this group. Ovarian cysts predominate over other abnormalities. This type of lesion has been referred to as "non-puerperal secretion,"^{23, 24} "periductal mastitis," "microcystic fibroadenomatosis,"²⁵ and "benign parenchymatous hyperplasia."²⁷ Nonpuerperal secretion and associated processes, which seem to be due to endocrine dysfunction and are akin to lactation, are frequently allied with abnormalities of the process, occurring as a sequel to it as a result of incomplete involution or from the continuation of the lactation. This syndrome is probably due to an ovarian dysfunction in which the normal cyclic secretion of hormones is absent. Such a condition is suggestive of an anovular cycle, a state that often occurs in the premenopausal period when these breast lesions may make their appearance.

Unfortunately, many of the lesions seen by the clinician are not so clear cut as those described above. There may be combinations of adenofibrosis and nonpuerperal secretion. Other cases show, in addition, cyst and papillomatous formation,²⁴ which may be superimposed on the two basic processes. Such a phenomenon occurs when the less complicated lesions are of long standing and are subjected to continuous or new stimulation. This group of mixed lesions leads to great confusion in diagnosis and interpretation of causative factors. At present, because of an incomplete understanding of these types, it is difficult to evaluate possible exciting factors. Lesions resembling the various types have been produced in animals by various hormones, particularly the estrogens. At any rate, it is possible

that factors concerned in the production of the more clear-cut lesions are involved in this heterogeneous group as well.

(To be concluded)

CASE 32401

PRESENTATION OF CASE

A sixty-three-year-old diabetic housewife entered the hospital because of abdominal swelling and pain in the right upper quadrant.

A week before admission the patient first noticed an intermittent pain in the right upper quadrant of the abdomen and occasionally a pain in the right thoracolumbar region. The pain was not influenced by food. The patient felt nauseated at times but did not vomit. The bowels moved daily in a normal fashion, and the stools became light yellow five days before admission. The urine became darker with the onset of this illness. Two days before admission the sugar reaction turned from green to brown. At the onset of the illness the patient noticed that the abdomen was increasing in size. The abdominal pain and swelling progressed gradually until the day of admission, when the pain became much severer. An injection given by a physician gave relief and the abdomen was painless at the time of entry.

The patient had had recognized diabetes for eleven years, during which she was seen frequently in the Out Patient Department. The glycosuria was usually well controlled, but six years before admission one toe became gangrenous and in the following years there were several hospital admissions for gangrene of the toes and suppuration at the sites of amputation. Early in the disease moderately increased deep reflexes of the lower extremities, bilateral Babinski reflexes and partial impairment of position and vibratory sensations were noted. There was no anemia, and the gastric acidity was normal. The last hospital stay, four months previously, had been for cellulitis of the right foot and ankle. The blood pressure had always been in the neighborhood of 190 systolic, 100 diastolic, and moderate cardiac enlargement had been present for several years. Aside from these findings and the infection, the physical examination at the last admission had been negative. The fasting blood sugar was 93 mg per 100 cc.

Physical examination showed an obese woman in no distress. The pupils were constricted and re-

sponded to accommodation, but had a paradoxical reaction to light, on former admissions they had been sluggish, but within normal limits. There were rales at the lung bases. There was a Grade I systolic murmur at the apex and base of the heart. The cardiac rhythm was regular. The abdomen was distended, and a fluid wave was elicited. Tenderness was confined to the right upper quadrant, where it was pronounced. The liver could not be definitely felt but was thought to be enlarged to the crest of the ilium. The tip of the spleen was palpable. The left fourth and fifth toes were missing, and there was a transmetatarsal amputation on the right. The legs were moderately edematous. Neurologic examination was negative.

The temperature was 98°F, the pulse 72, and the respirations 16. The blood pressure was 160 systolic, 70 diastolic.

Examination of the blood showed a hemoglobin of 15 gm per 100 cc and a white-cell count of 11,600, with 82 per cent neutrophils. The urine was yellow and had a specific gravity of 1.015. There was a +++ test for albumin, a ++ reaction for bile and a green sugar reaction. The sediment contained an occasional white cell per high-power field. The stools, which were tan and formed, gave negative guaiac reactions. The fasting blood sugar was 88 mg per 100 cc. The bilirubin was 2.2 mg per 100 cc direct, and 3.0 mg indirect. The cephalin-flocculation test was + in twenty-four hours and +++ in forty-eight hours. The total protein was 6.1 gm per 100 cc, with 4.0 gm of albumin and 2.1 gm of globulin. The nonprotein nitrogen level and the prothrombin time were normal. Abundant colon bacilli were cultured from the urine.

A paracentesis on the day after admission yielded 1500 cc. of cloudy, orange-colored fluid with a specific gravity of 1.010. There were 5400 white cells, most of which were neutrophils, and 900 red cells per cubic millimeter. Considerable fluid remained in the abdomen after the tap. The liver could not be palpated. An x-ray film showed the stomach to be distended with air. All abdominal structures were poorly outlined because of fat or fluid, or both. The spleen was slightly enlarged, but the liver shadow was not delineated. On the third day 300 cc of fluid was removed. Slight but definite icterus of the scleras and skin had appeared. The patient was apathetic and during the following day became confused. Many urine tests for sugar were blue or green, and the highest blood-sugar level was 195 mg per 100 cc. Forty units of protamine insulin were given daily. The arms and legs became cold and moist. The abdomen remained distended, and the temperature normal.

By the fifth hospital day the patient was not responsible and the jaundice of the scleras had increased. At noon the blood sugar was 261 mg per 100 cc, and the carbon dioxide 15.8 milliequiv per liter. Half an hour later she died quietly. At no

time was the pulse, respiration or temperature elevated

DIFFERENTIAL DIAGNOSIS

DR DANIEL ELLIS I do not believe that the diabetes as such was the cause of the immediate illness and death in this case. In the terminal stage there was acidosis, which I consider to have been due to whatever else the patient had and not to the fact that the diabetes was not well controlled. There is no indication of diabetic coma or diabetic acidosis.

This case, therefore, is primarily that of a woman who was known to have had diabetes, who on previous occasions had had repeated episodes of infection, and who was admitted to the hospital with a history of pain, swelling of the abdomen and increasing jaundice of approximately a week's duration. I still do not know what she had, and my final diagnosis will be given without too much conviction. The best I can do is to mention some of the possibilities.

About 50 per cent of the cases with ascites are on a cardiac basis. This woman had an elevated blood pressure, and probably had essential hypertension. There were rales at the lung bases, but the facts are stressed that at no time was there difficulty in respiration and that the pulse was not elevated or irregular. According to the record the systolic blood pressure was about 30 points below a previous reading. There was no evidence of venous distention at any time. If this patient had had cardiac failure, which might well explain the presumably enlarged liver, the abdominal pain in the region of the liver, the ascites and the edema of the feet, there should have been more evidence of the disease and of the discomfort that goes with heart failure. I cannot conceive of death from cardiac failure with the picture that is outlined here.

Cirrhosis of the liver is a possibility. The patient may have died of liver failure, but I do not believe that it was on the basis of cirrhosis. The only evidence of abnormal liver function is the cephalin-flocculation test. The prothrombin time, the serum protein, the albumin-globulin ratio, the red-cell count and the hemoglobin were normal, and the jaundice was minimal, although it gradually increased in severity. I do not believe that the terminal picture was due to portal cirrhosis or to hepatitis, which would have been an acute and fulminating one, and from the record I do not believe that an acute infectious process involving the entire parenchyma of the liver was present.

Neoplastic disease must be considered, although there is little evidence from the facts at hand. If she had cancer, it must have involved the abdominal viscera, causing obstruction of the portal circulation. Apparently there was no obstructive jaundice, no history of weight loss and no previous history of prolonged symptoms that might be attributed to a malignant neoplasm. The ascites, if caused by

cancer, could have been due either to peritoneal seeding or to obstruction of the portal vein or the inferior vena cava.

The question of infection arises. From time to time there was a chronic, suppurating process in the feet. Did the patient have amyloid disease? If the liver was enlarged, the enlargement might have been due to amyloid disease, but the fact that she had ascites to an increasing degree is slightly against it. Amyloid disease might account for the findings in the urine, however. All I can do at the moment is to mention that diagnosis as a possibility.

Could the patient have had tuberculosis? Tuberculous peritonitis might have caused such a picture, although usually with tuberculosis there is evidence of disease elsewhere. Also, the patient would probably have been febrile. The findings in the ascitic fluid are rather against tuberculosis. The fluid in a tuberculous peritonitis usually has a specific gravity of about 1.015, and the cells most frequently found are primarily of lymphocytic origin. Incidentally I should like to check the figures on the fluid. The specific gravity was 1.010, and the white-cell count was 5400. Someone must be wrong.

DR EARLE M. CHAPMAN Those are strong words, doctor. That is an important observation in this case. Where is Dr. Averill?

DR J. H. AVERILL I did the tests, and the figures are correct.

DR ELLIS That is all I wanted to know. I must say, then, that the terminal disease was one of intra-abdominal infection. Probably one of the reasons that the first paracentesis yielded only 1500 cc. of fluid is that the abdomen was large and distended and contained fluid that was pocketed, that is only an assumption, however. One might point out that the pain was due to stretching of the liver capsule, which may cause pain and on occasion simulates an acute abdominal emergency. As I mentioned previously, this type of pain, apparently severe enough to require morphine, occurs in right-sided cardiac failure or in an acute hepatitis. Possibly the morphine obscured the findings on admission. One must therefore consider the possibility of a ruptured viscus, obscured by the morphine, although I think that it is unlikely.

So far as the source of infection is concerned, I am driven back to the fact that there were repeated infections in the past, and although I am not sure that such a thing is possible, a pyelephlebitis of a septic nature may have occurred from repeated infection in the extremities. Perhaps the most logical diagnoses are a pyelephlebitis involving the liver, with septic abscesses, and peritonitis, and the terminal picture was one of overwhelming sepsis to such an extent that there was no rise in pulse rate and no great rise in the white-cell count, although the latter was definitely elevated, with 82 per cent neutrophils. The second choice is tuberculous peritonitis, with the obvious complications of diabetes,

Generalized arteriosclerosis and arteriosclerotic heart disease.

DR. WYMAN RICHARDSON I was going to discard the white-cell count and say that the patient had a glomerulonephritis initiated by a renal factor and perhaps a mild portal cirrhosis also in the background.

DR. ELLIS If a renal condition caused an illness of this degree and death, would not the nonprotein nitrogen have been elevated?

DR. RICHARDSON Was that determination made?

DR. ELLIS Yes, the nonprotein nitrogen was normal.

DR. JAMES TOWNSEND There was only one white blood cell per high-power field in the sediment. Is that not against pyelonephritis?

DR. RICHARDSON There were a ++++ test for diphtheria and abundant colon bacilli.

DR. ELLIS The albumin is consistent with acute infection elsewhere and dehydration.

DR. BENJAMIN CASTLEMAN The field is still wide open.

DR. JOHN GRAHAM I should like to ask Dr. Ellis if he has any opinion about the abnormal neurologic findings.

DR. ELLIS I could not make much out of them.

DR. GRAHAM What about the pupillary findings?

DR. ELLIS The pupillary findings on the last admission, I think, were due to morphine. The previous neurologic findings could be explained on an arteriosclerotic basis.

DR. CHAPMAN This was indeed a difficult case, and as I listened to Dr. Ellis I could appreciate how he felt. We had a disagreement on the service. There were four possibilities: heart disease, infection, cirrhosis and cancer. We excluded cardiac failure and infection, although we did not seriously entertain massive infection, as Dr. Ellis suggested. We were then left with cirrhosis and cancer and there we had the disagreement.

My interpretation was that the patient had been diabetic for years and had gone into cholemia. After the paracentesis was done we could not feel a large liver so that I interpreted it as a small, shrunken liver and thought that the cirrhosis had been present for a long time. The fluid was a transudate and not an exudate. The specific gravity was 1.010 and yet the cell count was high. How to explain this was the question. Dr. Averill took the other stand—that it was intra-abdominal cancer, with seeding throughout the peritoneum. He could not explain the low specific gravity any more than I could explain the large number of cells. Then came the point of explaining the urinary albumin. Did the patient have nephritis? I thought that she probably had a hepatorenal syndrome with a failing liver. With destruction of the liver protein massive albuminuria occurs, I should like to refer to an article by Thomas,* who calls attention to the presence of serum protein in the urine as a detoxifying process. In artificial nephritis in dogs Thomas

found that liver protein was first excreted and that tissue protein later joined the serum protein and both were excreted. With this mechanism in mind I postulated that the excessive proteins in the urine were liver and not body-tissue proteins.

DR. N. H. MARTIN† How do you explain the albumin-globulin ratio?

DR. CHAPMAN I cannot explain it.

DR. MARTIN In chronic cirrhosis the patient regenerates sufficient tissue to maintain a normal serum protein, but with loss of liver tissue the total protein ultimately drops below the maintenance level. If liver failure is acute there may be a short period when the patient lives on protein "capital," but then a fall in the total protein and a change in the albumin-globulin ratio occur, or death may come before this serum change.

DR. ELLIS Normal albumin-globulin ratios are frequently encountered in the presence of fatal hepatic damage. Within the last week we have seen a patient who died because of massive destruction of the liver by an infiltrating cancerous process. His death was obviously one of liver failure, and yet the liver-function tests a week before death were normal.

DR. TOWNSEND Dr. William C. Burrage suggests that this may have been the specific type of cirrhosis that is associated with diabetes—namely, hemochromatosis. Usually these patients have difficulty in controlling the diabetes over a long period. This history does not suggest hemochromatosis to me, but I should like to hear a discussion about that.

DR. CHAPMAN This woman had the most extraordinary pale, clear-white skin of anyone I have ever seen. We could not possibly entertain that diagnosis. It is true that she was jaundiced, but the jaundice developed only forty-eight hours before death.

DR. TOWNSEND Was the ascitic fluid examined for tumor cells?

DR. B. J. KENNEDY Yes, but no tumor cells were found.

CLINICAL DIAGNOSES

Diabetes mellitus
Cholemia
Abdominal cancer?

DR. ELLIS'S DIAGNOSES

Pylephlebitis, with multiple abscesses, of liver, portal obstruction and secondary peritonitis
Generalized arteriosclerosis
Arteriosclerotic heart disease
Diabetes mellitus, controlled

ANATOMICAL DIAGNOSES

Carcinoma of pancreas, with metastases to regional lymph nodes, liver, lungs and pleura

*Thomas, W. A. Source and role of urinary protein in nephritis. *J. A. M. A.* 97:1055, 1931.

†Of the Middlesex Hospital, London.

Thrombosis of portal vein and right hepatic artery

Massive infarction of liver, right lobe.

Infarcts of spleen and kidney

Cardiac hypertrophy, hypertensive type, mild

PATHOLOGICAL DISCUSSION

DR CASTLEMAN Autopsy showed a number of unusual findings. The heart was enlarged, weighing 450 gm. It showed mild hypertensive hypertrophy of the left ventricle. There was no evidence of heart failure. The liver was slightly enlarged, weighing 1800 gm, and presented on the surface a mottled appearance. There were numerous nodules, which seemed to be obviously carcinomatous, studded over its entire surface. They were not raised, as they usually are in carcinoma, but on cutting into them they appeared neoplastic. The liver surrounding the islands of tumor seemed softer and grayer than normal. When the liver was sectioned there was a marked difference between the right and left lobes. There was tumor in both lobes, but the intervening parenchyma in the right was soft and yellowish gray and the markings were completely obliterated, no central veins could be made out, and it had the appearance of a massive infarction. The left lobe showed tumor nodules but without any of the yellowish-gray softening, and the central veins were easily discernible. In the portal vein we found a large thrombus that extended somewhat into the splenic and somewhat into the superior mesenteric vein.

We know that portal-vein thrombosis produces partial infarction of the liver, in which one sees marked acute congestion microscopically but no necrosis of the liver cells to any degree. Ordinarily, when one finds infarction of the liver, one also expects to find a thrombus in the hepatic artery. That was looked for, and in the intrahepatic portion of the main right hepatic artery we found a fresh thrombus, which we believed to account for the complete infarction of the right lobe. There was no thrombus in the left branch. The combination of the portal-vein thrombosis and that of the right hepatic artery was probably responsible for the rapid development of cholemia. The carcinoma itself, I am sure, would not have produced the signs of cholemia. The primary source of the carcinoma was in the head of the pancreas. In addition to the liver there were metastases in most of the regional lymph nodes in the pleura and, on microscopic section, in the lung parenchyma. The source of the hepatic-artery thrombosis is still unsolved. There was a good deal of tumor surrounding the hepatic artery, and quite possibly pressure by the tumor produced thrombosis. Of course it may have been an embolus, and in favor of that theory was the finding of small infarcts in the spleen and kidney, we were unable to find any source in the aorta or heart, however.

DR WILLIAM MCK JEFFERIES Do you think that decompression from the abdominal paracentesis could have resulted in portal-vein thrombosis?

DR CASTLEMAN I do not believe so. The portal-vein thrombosis was fairly old, not so recent as the hepatic-artery thrombosis. The kidneys showed marked sclerosis, and in a few areas the glomeruli showed the intercapillary glomerulosclerosis that is seen in diabetes.

DR RICHARDSON Was there pyelonephritis?

DR CASTLEMAN No. The ascitic fluid, which was a transudate, was not due to neoplastic implants but was the result of the portal-vein thrombosis.

DR. ELLIS How about the nature of the ascitic fluid? I should like elucidation of these findings, that is, the low specific gravity and the relatively high white-cell count.

DR CASTLEMAN I do not know the answer.

DR RICHARDSON Was the specific gravity determined when the fluid was hot or cold?

DR AVERILL The test was made ten minutes after the tap, the fluid had probably cooled off somewhat.

CASE 32402

PRESENTATION OF CASE

A fifty-five-year-old Ukrainian-born restaurant porter entered the hospital because of severe hematemesis.

Eight months before admission the patient began to have a mild burning sensation in the epigastrium half an hour after heavy meals. This complaint never caused much distress or required medication. At that time he passed two black stools. A week before admission the burning sensation became worse, but was always relieved by a proprietary preparation containing bismuth. Every day for a week there were one or two loose black stools and the patient was increasingly weak. Six hours before admission on going to bed he felt weak and dizzy. He was awakened two hours later by nausea and vomited a large quantity of bright-red blood and dark clots with considerable violence. He then fainted and was unconscious for several minutes. He subsequently vomited blood once, but less violently. There was never any pain associated with the illness.

The patient had been chronically constipated for years and had lived on a diet of soup, stew and daily laxatives for the seven years before admission.

Physical examination showed the skin to be pale, dry and warm. The tongue was smooth, and the mucous membranes pale. The pulse was strong and regular. The heart, lungs and abdomen were normal, as was peristalsis.

The temperature was 98.6°F, the pulse 80, and the respirations 16. The blood pressure was 118 systolic, 65 diastolic.

Examination of the blood revealed a red-cell count

2,750,000, with 8 gm of hemoglobin, and a white-cell count of 12,500, with 90 per cent neutrophils. The urine was normal. The prothrombin time was 22 seconds (normal, 22 seconds), the nonprotein nitrogen was 47 mg and the total protein 5.3 gm per 100 cc. The stools were tarry and gave + + + + + guaiac reactions.

Whole-blood transfusions were given for two days, after which x-ray examination of the stomach and duodenum was made. The stomach was normal, but there was a defect in the duodenum that moved with peristalsis and had the appearance of a polyp. By the fifth hospital day the patient's condition was definitely worse despite 1000 cc of whole blood given daily. There was no more vomiting until the fifth day, but nausea was constant and the stools were always black. On that day the hemoglobin was 1 gm. After a transfusion the patient suddenly vomited 300 cc of blood, the pulse rose to 125, and the systolic pressure fell to 110. The pulse had returned to 100 by the next morning. The prothrombin time was 32 seconds (normal, 20 seconds), and the nonprotein nitrogen 84 mg per 100 cc. Gastric x-ray studies on the sixth day showed a normal stomach. The filling defect in the duodenum had disappeared and was assumed to have been a blood clot.

An operation was performed on the seventh hospital day.

DIFFERENTIAL DIAGNOSIS

DR. PETER SARRIS. This history is rather simple and direct in comparison with most histories that are presented here. It is equally striking by the absence of any positive data on which to make a diagnosis. In this case a diagnosis must be made by exclusion rather than by the more satisfactory method of presenting positive evidence.

Before discussing the differential diagnosis I should like to point out a few things in the history and physical examination. This eight months' story of a mild burning sensation only after heavy meals is not particularly impressive or diagnostic. Many people have a mild burning sensation after a heavy meal, especially if the meal consists of soup, stew and a daily laxative. The symptom is important, however, in view of the fact that it was associated with black stools eight months before admission. Such stools, as information given by a patient, are not always significant. When many leads are traced it is often found that the patient did not have really tarry stools. In this case the statement can be accepted because the patient later had unquestionable melena and was therefore familiar with the appearance of tarry stools. The onset can thus be dated eight months previously, but I do not find any information that helps to make a differential diagnosis. The only helpful point is the massive gastrointestinal hemorrhage. The record mentions vomiting with considerable violence. To me that

means that the stomach was probably in good tone and not one of those atonic, dilated, chronically obstructed stomachs with consequent overflow vomiting. It might also mean that the clots produced partial pyloric obstruction. The constipation I cannot tie up with the rest of the story. Once started with cathartics, the patient probably had to stick to them. That, in addition to the diet, may have been significant in producing a vitamin deficiency. I shall return to that later.

The physical examination really contributes nothing except the statement that the patient was anemic, confirming the fact that hemorrhage had occurred, and the history indicates that the patient was not in shock on admission; the pulse was 80, and the blood pressure was satisfactory.

The laboratory data are also of little assistance except to confirm the anemia. The white-cell count and the markedly increased neutrophil count confirm the recent hemorrhage. The urine was normal. I take it that that was an aggregate report. Apparently several examinations were done to exclude any urinary insufficiency or nephritis, which might conceivably tie up with the gastrointestinal bleeding. The prothrombin time was 29 seconds,—later 32 seconds,—which is slightly elevated but not in the range that would explain bleeding from a prolonged prothrombin time per se. The nonprotein nitrogen was 47 mg and later 84 mg per 100 cc, which is, of course, definitely abnormal. Anyone with major gastrointestinal bleeding, however, is entitled to it, because not only the accompanying dehydration and the periodic hypotension but also the ingestion of blood itself raise the nonprotein nitrogen, even if the patient has properly functioning kidneys and is otherwise normal. I therefore do not ascribe any particular significance to the high nonprotein nitrogen in this patient.

The course in the hospital suggests little more than that massive bleeding continued. The patient required a transfusion of 1000 cc of blood daily and after five days of this regime the hemoglobin was the same as it was on the day of admission, presumably, 5000 cc of blood had been lost in five days.

In this type of bleeding one can dispose of a number of diagnoses because of lack of evidence, such as poisoning and chronic ulceration from tuberculosis or syphilis, although in such conditions massive bleeding sometimes occurs. There is no massive bleeding with uremic ulcers and the acute ulcers that accompany acute infectious disease. Jaundice from any cause may lead to massive hematemesis. Blood dyscrasias such as leukemia and purpura also produce massive bleeding. There is no evidence of blood dyscrasias as from the blood smear, however, and it is unusual for them to cause so much gastric bleeding without evidence of a hemorrhagic tendency somewhere else. These diseases can all be excluded either because of lack of evidence or because the diagnosis can be made only when there is a

specific finding pointing to that diagnosis. The bleeding from a high prothrombin time, which I mentioned earlier, can be excluded since it was not sufficiently high in this case to produce bleeding per se, although it might have contributed to the aggravation of the bleeding. Furthermore, in cases of bleeding due to an elevated prothrombin time, jaundice or sepsis is almost always apparent as the cause.

The source of bleeding can be limited to a location between the lower esophagus and the duodenum. The combination of melena and hematemesis fairly well limits the lesion to that area, which of course is a large area and can include a great deal of disease. In the course of bleeding from duodenal ulcer melena usually precedes hematemesis and often there is only melena, whereas in bleeding from the esophageal varices the reverse is true.

Once in a while one sees massive hemorrhage from a gallstone that has perforated into the duodenum, usually from a gangrenous gall bladder. There was no evidence of gall-bladder disease in this case, and certainly such an episode of perforation into the duodenum would have been accompanied by pain, which was absent. In such cases, the bleeding is incidental.

One more cause, idiopathic bleeding, when nothing else is found, can be excluded. In some patients with repeated and marked bleeding even after part of the stomach is resected the bleeding continues and no explanation is ever found. I do not believe that that is the answer in this case. Presumably, Dr Mallory will confront us with some pathologic lesion. Cancer, peptic ulcer, esophageal and gastric varices, gastritis and benign gastric tumors remain.

It might be wise to see the x-ray films at this point.

DR MILFORD D SCHULZ: The x-ray films taken in this case are missing.

DR SARRIS: I think it fair to ask, then, if the roentgenologist was satisfied with the second film showing a completely normal stomach and duodenum, excluding the possibility suggested by the first film of a polyp that might have receded into the fundus of the stomach and therefore become invisible.

DR SCHULZ: That is a possibility, of course, but the fact that the disappearing lesion was assumed to be a blood clot indicates a careful search for some explanation.

DR LEWIS K DAHL: I might amplify Dr Schulz's remark by saying that Dr Schatzki considered his examination to be reasonably satisfactory.

DR SARRIS: I take it that gastroscopy was not done and that it was regarded as inadvisable.

DR TRACY B MALLORY: I believe that that is true.

DR SARRIS: I also take it that no cellular studies were made on the gastric contents. Such studies are becoming increasingly valuable for early diagnosis.

DR MALLORY: No such information is given.

DR SARRIS: I believe that gastric cancer is the

least likely diagnosis. First of all, it accounts for only 5 per cent of the massive hemorrhages, and there was no suggestive history, there was no weight loss, and no weakness except after massive bleeding. Furthermore, I believe that a gastric cancer is not likely to have been missed by x-ray examination.

Peptic ulcer must be more seriously considered because it accounts for 75 per cent of massive hemorrhages of this type. The history is reasonably consistent with it, although the burning sensation was mild only after heavy meals. I do not recall seeing such a massive hemorrhage from duodenal ulcer in which some deformity of the duodenum—a crater, spasm or a similar lesion—was not demonstrated by x-ray examination. This patient had two examinations. The lesion could have been a small peptic ulcer in the stomach, which is sometimes missed in the x-ray film.

Esophageal varices, which account for 5 to 10 per cent of massive hemorrhages of this type, are secondary to cirrhosis, hepatic insufficiency or previous portal or splenic thrombosis. Many patients enter the hospital for the first time because of massive bleeding from esophageal varices, and the diagnosis of portal cirrhosis is made. Usually, some abnormality, such as an enlarged spleen, is disclosed by the physical examination or by laboratory tests, such as liver-function studies, which were not done in this case. The most important feature against esophageal varices is the x-ray film, which rarely misses them. Gastric varices offer a different problem, since they can be missed by x-ray examination. I remember a case with repeated hematemesis in which several x-ray films were taken and nothing was demonstrated. At operation, performed with Dr Richard H Sweet, the patient was found to have varices limited to the fundus. Gastric varices must therefore be considered, but there is no evidence for the disease that produced the varices. Gastritis, with single or multiple erosions, which has been encountered in several cases, could well have been present, the erosions being superficial and peptic in nature but not deep enough to produce a lesion visible on x-ray study.

The last consideration is benign gastric tumor, which includes adenoma, leiomyoma, hemangioma, neurogenic fibromas and lipoma. Excessive bleeding is characteristic of such tumors, particularly the adenomas, the leiomyomas and the hemangiomas. They may be pedunculated, and when I first read this history, before I reached the last paragraph, it seemed certain that the diagnosis was an adenoma that had prolapsed into the duodenum. That is why I was anxious to determine the possibility of a polyp. But the roentgenologists apparently believed that the possibility of a polyp that receded into an invisible position was much less than that of a blood clot. Therefore, if this was a benign tumor of the stomach, there was no conclusive x-ray evidence.

In conclusion the diagnosis depends on the consideration of which lesion that I have mentioned is not only frequent enough to be considered but also easiest to be missed by x-ray examination. Benign tumors are often overlooked unless they are large or have a large ulceration, which they sometimes do. If the tumors are small and are not deeply ulcerated they are missed because they do not disturb peristalsis and do not usually produce spasm and because the mucosal pattern is often normal. I cannot make any final decision. If it turns out to have been a benign tumor, the adenomas and leiomyomas are the commonest occurrence. The bleeding tumors most frequently encountered are the hemangiomas and the adenomas, which are my first choice. My second choice is a gastritis, with single or multiple superficial erosions. My third choice is gastric varices.

DR. EDWARD B. BENEDICT: Nine times out of ten, in a massive hematemesis, one would be correct in saying that the lesion was a benign peptic ulcer. I cannot quite agree with Dr. Sarris about the x-ray finding. I can recall 3 cases within a few years with massive hematemesis in which, in spite of an entirely negative x-ray examination, benign peptic ulcers were present.

DR. SARRIS: In the stomach?

DR. BENEDICT: Yes, in the stomach. In 1 case, in which the ulcer was prepyloric, gastroscopy demonstrated nothing. Another ulcer was in the upper part of the stomach, and the patient was not gastroscopied. The third was in the midpart, and gastroscopy a month before operation showed gastritis but did not show the tiny ulcer that was bleeding.

DR. SARRIS: The point that Dr. Benedict has made is well taken. I included a small benign peptic ulcer with the diagnosis of gastritis with single or multiple superficial erosions, because the small benign gastric peptic ulcers are to me similar to the superficial erosions in some cases of gastritis. Both conditions are often missed by x-ray examination.

CLINICAL DIAGNOSIS

Leiomyoma of stomach

DR. SARRIS'S DIAGNOSIS

Benign gastric tumor

ANATOMICAL DIAGNOSIS

Cirsoid aneurysm of left gastric artery, with secondary peptic erosion

PATHOLOGICAL DISCUSSION

DR. MALLORY: We hardly expected Dr. Sarris to make the diagnosis because this case presented a lesion that is unique in the experience of this laboratory.

Will you tell what you found at operation, Dr. Hamlin?

DR. EDWARD HAMLIN, JR.: On opening the abdomen we found the upper gastrointestinal tract filled with blood and nothing else. We thought seriously for a time that we were dealing with idiopathic bleeding, which Dr. Sarris mentioned. The third part of the duodenum and the stomach were carefully inspected. We opened the stomach along the antrum and found a great deal of blood and nothing else. While we were cogitating — the

FIGURE 1 Photomicrograph of the Large Eroded Vessel in the Submucosa, with Thrombus Formation

stomach was suspended between forceps — we noted blood accumulating in the upper part of the stomach, and that limited the field. Going over it carefully again we found a minute, actively bleeding speck, which was partially blood clot, about two thirds of the way from the pylorus to the fundus on the posterior wall. This was resected.

DR. MALLORY: The gross specimen that we received showed a small projecting red mass, which was evidently a thrombus overlying an artery in the submucosa. On dissecting the specimen further it was evident that an unusually large branch of the left gastric artery — as large as the main artery itself — came up through the muscularis into the mucosa for a distance of perhaps 0.5 cm and then turned around and bent down again to penetrate the muscularis once more. This vessel was sclerotic and tortuous, and we classified it as a cirsoid aneurysm. The mucosa over the artery and one side of its wall were entirely eroded away (Fig. 1). I suppose that the pressure of this abnormally large vessel immediately beneath the mucosa had led to ulceration of the mucosa, peptic in character, with the subsequent massive hemorrhage.

Whether this represents a congenital abnormality of the vessel or a developmental one I do not know any way of determining.

REALISM VERSUS WISHFUL THINKING

Organized medicine in this country has become increasingly conscious that a large section of the public holds it in low regard. This has been a disturbing thought to the leaders in the profession, as well as to the rank and file, and the average physician is apt to inquire why it is that, although as an individual he seems to be well thought of by those he serves, his collective acts, as expressed through the organizations that he and his colleagues comprise, are held in such low esteem. Is the physician a dual personality—a sort of Dr. Jekyll when serving the public in his individual capacity and Mr. Hyde when he acts in concert with his fellows?

Has organized medicine lost its democratic character? As a matter of fact, the pattern of democracy nowhere in this country is more closely followed

than it is in the conduct of the business of the majority of medical societies. Who can truthfully say that the House of Delegates of the American Medical Association is not concerned in the democratic spirit, either in its formation, in the methods attending its deliberations or in the conclusions it arrives at? If this body does not follow the democratic plan, neither then does the Congress of the United States, after which it was and continues to be closely patterned.

Can it be said that the democratic process has ceased to function in the Massachusetts Medical Society? Here, again, over the years democracy has grown and expanded. As an example, three of its most important committees—the Committee on Public Relations, the Committee on Legislation and the Executive Committee of the Council—are composed of a representative of each of our eighteen district societies. It may well be that the apparent ill repute of the Society in the minds of the public is conditioned by the indifference that some physicians show toward the conduct of the Society's affairs. This does not, however, connote a real lack of support any more than does the average citizen's attitude of indifference to the actual management of his government.

There seems to be little to support the dual personality theory. Nor does it seem likely that organized medicine has fallen in esteem because the public believes that it has ceased to walk in the democratic way.

At a meeting of the House of Delegates of the American Medical Association held in July at San Francisco, the delegates were informed of a particular activity that had been conducted under the auspices of the Board of Trustees, which took notice of the suspicions regarding public relations. A firm prominent and skilled in determining public opinion was engaged to determine whether these suspicions had any foundation in fact and if so what was to be done about it. On the one hand, this effort confirmed the popularity of the individual physician, and on the other, the low esteem in which he and his fellows are held as an organized group.

In an endeavor to find the answer to what seemed like a contradiction, those making the survey examined the entire setup of the American Medical Association. They found in the various scientific

activities of the organization so much in the interest of the public good as to constitute a veritable gold mine from the standpoint of public relations but they also learned that the public knew nothing about such treasure. Most people had heard of the American Medical Association, but principally as an organization that was working for the defeat of such legislation as the Wagner-Murray-Dingell Bill

The advice looking toward the remedy of this situation was simple. The people should be told about these scientific activities all of which are so definitely in their interest. They should be told in a language that is easily understood, they should be told at times that are opportune, and they should be told often. It should, however, be recognized that, although this remedy is simple, its proper application requires the services of a person with special experience and skill and that the job will be well done in proportion to the training and ability of the person selected to do it.

The program thus outlined was adopted by the House of Delegates. Whoever is chosen to carry out the plan will work in close harmony with the secretary and the general manager of the American Medical Association and with all its various bureaus and councils.

This is an experiment that offers much promise. It is realism as opposed to wishful thinking, it properly recognizes the value of a well informed public — an asset that has been developed by many organizations during the past ten or twenty years. State medical societies should watch this experiment closely, for in its operation may be found the answer to certain of their own difficulties.

TOXICITY OF TRIDIONE

INFECTIOUS diseases are not the only ones that benefit from chemical research. Even the Hippocratic disease, epilepsy, profits from the synthesis of new compounds. Latest encouragement comes from the use of a drug, 3,5,5-trimethylvloxazolidine-2,4 dione, the trade name of which is Tridione. The therapeutic peculiarity of this chemical is its nearly specific effect on a particular group of seizures, the so-called "petit-mal triad" — petit mal, akinetic seizures and myoclonic jerks. In one group of 166

patients treated at the Children's Hospital in Boston, two thirds were freed or almost freed of this particular type of seizure. Grand-mal seizures, on the other hand, were not helped and often became more frequent. Because the drug is of specific value for clinical syndromes associated with the alternate spike and wave of the electroencephalogram, it offers intriguing opportunity for further studies.

The more high-powered the weapon of offense, the greater the possibilities of harm if it should backfire. Peculiar reactions may accompany the use of Tridione. Generalized skin rashes are frequent but do not become serious if the drug is discontinued promptly and reinstated gradually. Photophobia (hemeralopia) is a peculiar, but apparently harmless, side effect for which there is as yet no explanation. A more disquieting complication is the occasional appearance of blood dyscrasias. Symptomless leukopenia or eosinophilia has been noted in a few patients,¹ and in two cases recently reported there was aplastic anemia with agranulocytosis, uncontrollable bleeding and death.^{2,3}

An allergic or toxic reaction of a patient to a given drug is always a lively possibility. Withholding medicines that have ever caused serious reactions would work misfortune on the many who require those medicines. Tridione medication has resulted fatally for only one of some 5000 patients being treated. This ratio can be increased if physicians, forewarned, will take the necessary precautions. These are as follows: prescribe Tridione only for the type of seizure that can be helped, — namely, petit mal (pykno-epilepsy), myoclonic jerks and akinetic seizures, — and for patients without a history of blood dyscrasia, give no more than the amount needed to control petit mal, inquire for weakness, pallor, dyspnea, undue bleeding and hemorrhagic skin eruptions, and examine the blood monthly and stop medication if the platelets are substantially reduced, if the white-cell count falls below 4000 or the percentage of neutrophils below 50 per cent or if there is pronounced anemia. Having taken these precautions, the physician can give tridione to his young patients who are subject to petit mal with the expectation that approximately two thirds of them will receive substantial relief from this type of seizures.

MASSACHUSETTS MEDICAL SOCIETY

BUREAU OF CLINICAL INFORMATION

All secretaries of various medical groups, such as special societies and alumni associations, are requested to notify the Bureau of Clinical Information regarding scheduled meetings, annual dinners and so forth. If such data are on file, it is hoped that duplication of dates can be avoided.

DEATHS

ALMY — Thomas Almy, M.D., died September 6. He was in his sixty-third year.

Dr. Almy received his degree from Harvard Medical School in 1909. He was formerly chief of the staff of Union Hospital, and was a member of the New England Obstetrical and Gynecological Society and the New England Pediatric Society and a fellow of the American Medical Association. He was a diplomate of the American Board of Obstetrics and Gynecology.

His widow survives.

BAILEY — Marshall H. Bailey, M.D., of Norwell, died September 18. He was in his eighty-eighth year.

Dr. Bailey received his degree from the College of Physicians and Surgeons, Baltimore, in 1893.

COMMENT

Diseases reported at an incidence above the seven-year median included anterior poliomyelitis, diphtheria, German measles and measles.

Although above median prevalence, poliomyelitis had an incidence of about half that of last year.

Diphtheria showed the highest August prevalence of the last ten years. This is the fourth consecutive month in which such an increase has taken place.

Diseases reported below the median prevalence included meningococcal meningitis, mumps, scarlet fever and whooping cough.

Lobar pneumonia was again at a record low for the seventh consecutive month.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Anterior poliomyelitis was reported from Arlington, 1, Auburn, 1, Beverly, 1, Blackstone, 1, Blandford, 1, Boston, 5, Brookfield, 3, Carlisle, 1, Dedham, 1, Framingham, 1, Franklin, 1, Harwich, 1, Holyoke, 1, Hull, 1, Lancaster, 1, Lowell, 3, Lynn, 1, Lynnfield, 1, Malden, 2, Marblehead, 1, Medford, 1, Methuen, 1, Middleboro, 1, New Bedford, 1, North Adams, 1, North Attleboro, 2, Northampton, 3, Norwood, 1, South Hadley, 1, Somerville, 1, Walpole, 1, Washington, 1, Watertown, 2, Wellesley, 1, Weston, 1, Worcester, 13, Wrentham, 1, total, 62.

Diphtheria was reported from Boston, 10, Braintree, 1, Cambridge, 1, Mansfield, 1, New Bedford, 2, Somerville, 3, Sudbury, 1, Waltham, 1, total, 20.

Dysentery, amebic, was reported from Quincy, 1, total, 1. Dysentery, bacillary, was reported from Boston, 1, total, 1. Lymphocytic choriomeningitis was reported from Agawam, 1, total, 1.

Malaria was reported from Boston, 7, Bourne, 2, Cambridge, 2, Clinton, 1, Haverhill, 1, New Bedford, 1, Oxford, 1, Somerville, 1, total, 16.

Meningitis, meningococcal, was reported from Boston, 2, Canton, 1, Lawrence, 1, total, 4.

Meningitis, Pfeiffer-bacillus, was reported from Beverly, 1, Medford, 1, total, 2.

Meningitis, other forms, was reported from Springfield, 1, total, 2.

Meningitis, undetermined, was reported from Amesbury, 1, Salem, 1, Shrewsbury, 1, total, 3.

Rocky Mountain spotted fever was reported from Dennis, 1, total, 1.

Salmonella infections were reported from Beverly, 3, Boston, 2, Chelsea, 1, Lawrence, 1, Lynn, 23, Malden, 1, Marblehead, 5, Newton, 2, Peabody, 1, Quincy, 1, Springfield, 1, Swampscott, 1, Topsfield, 1, Winchester, 1, Yarmouth, 1, total, 45.

Septic sore throat was reported from Boston, 7, Brookline, 1, Greenfield, 1, Holbrook, 1, Newburyport, 1, Somerville, 1, total, 12.

Tetanus was reported from Quincy, 1, total, 1. Trichinosis was reported from Boston, 2, Norwood, 1, total, 3.

Typhoid fever was reported from Boston, 2, Chicopee, 2, Marblehead, 1, Randolph, 1, total, 6.

Typhus fever was reported from Malden, 1, total, 1.

Undulant fever was reported from Adams, 1, Dighton, 1, New Ashford, 1, Southbridge, 1, Westminster, 1, Worcester, 1, total, 6.

BOOK REVIEWS

Anatomy as a Basis for Medical and Dental Practice By Donald Mainland, M.B., Ch.B., D.Sc., F.R.S.E., F.R.S.C. 8°, cloth, 863 pp., with 61 illustrations and 11 tables. New York: Paul B. Hoeber, Incorporated, 1945. \$7.50.

It is refreshing to read a textbook of anatomy, such as this, written in a manner that retreats from the conventional method of presentation. Students of medicine and dentistry will find a copy of this book an asset throughout their professional career. A student, soon to begin a course in anatomy, will find himself well oriented in this subject matter if he carefully reads and perhaps rereads Part I, which succinctly discusses the aims and methods of anatomic studies, and then turns to Appendix III, to become acquainted with important hints on how to read and write articles pertaining to anatomy. Armed with the understanding that these chapters will supply, the student is led to the study of Part II, presenting general anatomy, which begins with a considera-

tion of the body as a whole and proceeds to the discussion of bones, joints, muscles and fascias, blood and lymphatic vessels, nerves, skin and appendages. Part III concerns regional anatomy, the upper and lower limbs, thorax, abdomen, head and neck, back, brain and spinal cord and the autonomic nervous system. The reviewer wishes to draw special attention to the appendices, which deal with subjects such as radiology, postnatal ossification of limbs, normal weights of organs, tooth eruption dates, adult pelvic dimensions and segmental cutaneous nerve supply. Excellent references are given for each chapter, and a good index is supplied.

The volume as a whole has much merit and the author succeeds in offering his readers a well written, instructive and provocative book.

The Autobiography of Science. Edited by Forest R. Moulton, Ph.D., Sc.D., and Justus J. Schifferes. 8°, cloth 666 pp. Garden City, New York: Doubleday, Doran and Company, Incorporated, 1945. \$4.00.

It may be said that science had its beginnings in the recording of astronomical observations in Babylonian times, twenty centuries before the beginning of the Christian Era, and that its development has been international in scope, embracing all peoples and languages.

The compilers of this autobiography of science have brought together selections of all countries and all times—from the hieroglyphics of the ancient Egyptians and the *Old Testament* story of the Creation to the modern period of Osler, Cannon and Cushing. The book is fundamentally an anthology of the key passages from the master works of all sciences.

From an original list of three hundred authorities it was found necessary, because of space limitation, to reduce the number to a hundred, and in so doing the compilers were guided by two criteria: their importance as turning points in the history of science and their readability. They also attempted to determine the best thing a person ever wrote about the most important thing he or she ever did, the greatest consideration being given to persons whose work seemed to chart the main stream of the development of scientific thought. Three of the authors quoted are women: Lady Mary Wortley Montagu, Florence Nightingale and Madame Curie. The selections are in general arranged in chronological order by periods under eight headings, beginning with 'Science Is Born (Antiquity)' and concluding with 'Science Sires the Twentieth Century'.

The original texts of fifty-five of the selections, which were in a language other than English, are presented in translations by modern scholars, with the single exception of Cuvier, of whose work a new translation is offered. For the most part the writings are in simple words, easy to understand and to follow in their context. Only eleven of the scientists quoted write in a manner that is slow or hard to read. It is the impression of the compilers that there are fewer than a hundred unusual scientific words among the more than two hundred and fifty thousand words comprising the volume. In only one instance, Einstein, was it considered necessary to provide a special vocabulary.

In preparing the texts for publication the general reader has been kept in mind rather than the specialist, and the final editing has been done in the style of the best current American usage. Mathematical notation and symbolism have been omitted, but mathematical reasoning and theory necessary to the theme have been included.

The selections of each author quoted are preceded by a short biographic commentary.

Of the selections, fifty are on biologic and medical subjects, and of this number thirty-four are medical or of medical interest. The second selection quoted comprises excerpts from the Egyptian, Edwin Smith and Ebers papyri. The second to the last selection is Harvey Cushing's quoted "Homo Chirurgicus," which is given in full. The medical selections are all from outstanding, well known names in medicine: Hippocrates and Galeo in antiquity, Gui de Chauliac and the Regimen Sanitatis of Salerno in the Middle Ages, Leonardo da Vinci, Paracelsus, Fracastorius, Paré, Vesalius and Harvey in the Renaissance, Leeuwenhoek and Fauchard, the dentist, in the seventeenth and early eighteenth centuries, and Benjamin Franklin, Lady Montagu, Jenner, Laënnec, John Snow, Beaumont, Holmes, Crawford Long, W. T. G. Morton,

Pasteur, Lister, Florence Nightingale, Sedgwick, Roentgen, Freud, Osler, Cannon and Cushing in the later years.

This book may be used as a reference and source book, as a narrative or as a textbook on the history of science. It should be in all libraries, public and private, general and special, and is especially recommended for all medical libraries and for all persons interested in the history of medicine.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

The Way of an Investigator: A scientist's experiences in medical research. By Walter B. Cannon, M.D. 8°, cloth 229 pp. New York: W. W. Norton and Company, Incorporated, 1945. \$3.00.

The late Dr. Cannon, in this semipopular book, has written an autobiographical account of his work and at the same time has given a description of how the scientific investigator goes about doing his job.

Pulmonary Edema and Inflammation: An analysis of processes involved in the formation and removal of pulmonary transudates and exudates. By Cecil K. Drinker, M.D., D.Sc., professor of physiology, School of Public Health, Harvard University, Boston. The Nathalie Gray Bernard Lectures delivered at the Bowman Gray School of Medicine, Wake Forest College, Winston-Salem, North Carolina, in December, 1944, together with a fifth chapter on artificial respiration. Monograph No. 7, Harvard University Monographs in Medicine and Public Health. 8°, cloth, 106 pp., with 27 illustrations. Cambridge: Harvard University Press, 1945. \$2.50.

Dr. Drinker analyzes the formation and removal of pulmonary transudates and exudates. He also discusses the prevention and treatment of lung edema, and in the final chapter he reviews the problems and techniques of artificial respiration.

The Bacterial Cell: In its relation to problems of virulence, immunity and chemotherapy. By René J. Dubos, George Fahyao Professor of Comparative Pathology and professor of tropical medicine, School of Medicine and School of Public Health, Harvard University, and member of the Rockefeller Institute. With an addendum by C. F. Rohinow, Straughways Laboratory, Cambridge, England. Monograph No. 6, Harvard University Monographs in Medicine and Public Health. 8°, cloth, 460 pp., illustrated. Cambridge: Harvard University Press, 1945. \$5.00.

This important book describes the organization of the structural and physiologic components of the bacterial cells and interprets the phenomena of virulence, immunity and chemotherapy in terms of cellular organization. The present study utilizes not only direct microscopic methods but also the information derived from indirect methods, based on the physicochemical, physiologic and immunologic behavior of bacteria. This monograph should be in all medical and biologic libraries. An extensive bibliography is appended to the text.

Physical Chemistry of Cells and Tissues. By Rudolf Höber, University of Pennsylvania School of Medicine. With the collaboration of David I. Hitchcock, Laboratory of Physiology, Yale University School of Medicine, J. B. Bateman, Mayo Clinic, David R. Goddard, University of Rochester Biological Laboratories, and Wallace O. Febo, University of Rochester School of Medicine and Dentistry. 8°, cloth, 676 pp. Philadelphia: The Blakiston Company, 1945. \$9.00.

This comprehensive monograph is divided into eight principal sections. The first is devoted to a discussion of selected principles of physical chemistry applicable to the study of cell physiology. The following sections on the molecule, protoplast, cellular activity, respiration, contractility, passive penetration and active transfer to animal and plant tissues. The work is well documented, with selected references to the subject, and has adequate author and subject indexes. This monograph should be in all medical and related libraries.

A Manual of Surgical Anatomy By Tom Jones and W C Shepard Prepared under the auspices of the Committee on Surgery Division of Medical Sciences, National Research Council 4th, cloth, 195 pp, illustrated Philadelphia and London W B Saunders Company, 1945 \$5 00

This latest of the series of military surgical manuals is without text and has been prepared especially for surgeons in the field

Clinical Biochemistry By Abraham Cantarow, M D, professor of physiological chemistry, Jefferson Medical College, and Max Trumper, Ph D, Lt Commander, H(S)USNR, Naval Medical Research Institute, National Naval Medical Center, Bethesda, Maryland Third edition, revised 8th, cloth, 647 pp, with 29 illustrations Philadelphia and London W B Saunders Company, 1945 \$6 50

This authoritative textbook has been thoroughly revised to incorporate the progress in biochemistry during the five years that have elapsed since the publication of the second edition The volume considers many new tests and new subjects, including classifications of jaundice, physiology of gastric and pancreatic secretion and methods for the study of deficiency in the various vitamins, a chapter dealing with hormone assay and endocrine function has been added The authors have attempted to present controversial subjects in an impartial manner, supplemented by an expression of personal opinion The last chapter constitutes an outline of chemical abnormalities in various disorders, with pertinent page references A comprehensive index concludes the volume Selective bibliographies are attached to each chapter The material is well organized, and this book should prove valuable for reference purposes

NOTICES

ANNOUNCEMENTS

Dr Thomas W Botsford announces the opening of his office for the practice of general and pediatric surgery at 1101 Beacon Street, Brookline

Dr Donald T Chamberlin announces the opening of his office at 422 Beacon Street, Boston, for the practice of diseases of the digestive system

Dr Frederick C Irving announces the removal of his office to 1180 Beacon Street, Brookline

Dr John Ellis Knight announces his return from service with the armed forces and the reopening of his office at 520 Commonwealth Avenue, Boston

Dr L Tillman McDaniel announces his return to the practice of internal medicine at 12 Bay State Road, Boston

Dr James F McDonough announces the opening of his offices for the practice of obstetrics and female diseases at 15 Dix Street, Winchester, and 1101 Beacon Street, Brookline

Dr Elsie S Neustadt announces the opening of an office for the practice of psychiatry and neurology at 27 Avon Way, Quincy

Dr Ian P Rak announces his return to the practice of psychiatry and neurology at 422 Beacon Street, Boston

Dr Eugene Suzedell announces his return from military service and resumption of practice at 59 Coddington Street, Quincy

Dr Aldo G Verde, having returned from service with the United States Navy, announces the opening of his office for the general practice of medicine and surgery at 676 Adams Street, Dorchester

VAN METER PRIZE AWARD

The American Association for the Study of Goiter again offers the Van Meter Prize Award of three hundred dollars and two honorable mentions for the best essays submitted concerning original work on problems related to the thyroid gland Provided essays of sufficient merit are presented in competition, the award will be made at the annual meeting of the association, which will be held in Atlanta, Georgia, on April 3, 4 and 5, 1947

The competing essays may cover either clinical or research investigations, should not exceed three thousand words in length and must be presented in English, a typewritten double-spaced copy should be sent to the corresponding secretary, Dr T C Davison, 207 Doctors' Building, Atlanta 3, Georgia, not later than January 1, 1947 The committee that will review the manuscripts is composed of men well qualified to judge the merits of the competing essays

A place will be reserved on the program of the annual meeting for presentation of the winning essay by the author if it is possible for him to attend The essay will be published in the *Proceedings* of the association This will not prevent its further publication, however, in any journal selected by the author

SCARLET FEVER

An Epidemiologic and Bacteriologic Study of Cases Occurring in a Small Community

A. DANIEL RUBENSTEIN, M.D.,* AND GEORGE E. FOLEY†

BOSTON

THE serologic classification of the hemolytic streptococcus has often been applied to the study of more or less circumscribed outbreaks of scarlet fever and other streptococcal infections¹⁻⁴ and to the investigation of samples of endemic cases occurring during the so-called "streptococcus season" in a given community.⁵⁻⁸ There are, however, relatively few reports in which all or nearly all the endemic cases of scarlet fever occurring in a community have been studied bacteriologically as well as epidemiologically.

Perhaps the most complete information on the scarlet fever occurring in individual communities during a stated period is contained in the report of Schwentker, Janney and Gordon,⁹ who performed bacteriologic and epidemiologic studies on scarlet fever in several villages in Rumania.

Studies in schoolrooms¹⁰ and in families¹¹ suggested the hypothesis that the variety of serologic types of hemolytic streptococci recovered from patients when scarlet fever is endemic may be composed of innumerable so-called "pure-type" outbreaks occurring in basic units of the population.⁵⁻⁸ The sudden appearance of scarlet fever in a rural community that, except for a single case, had been free of this infection for a year was regarded as an excellent opportunity for further investigation of the transmission of this disease, the serologic classification of the hemolytic streptococci being utilized at the same time.

GENERAL DESCRIPTION

Ipswich, where the present studies were done, is a community with a population of 6611, situated on the northern coast of Massachusetts. Milk is supplied by several dealers, some of whom market raw milk. In 1945 the town had a total of 930 school children in attendance at four elementary

schools (three public and one parochial) and one high school. A single local theater attracts children from several surrounding communities. Children are discouraged from attending the theater when contagious diseases are prevalent and school is in session, but there are no restrictions during vacation or recess periods.

During the interval between January 2 and May 24, 1945, a total of 94 cases of scarlet fever was reported from this community, in contrast to 1 case reported in 1944 and 15 cases reported in 1943. Cases were scattered throughout the community, with no correlation with any of the various milk routes. Interestingly enough, one of the early cases due to Type 1 hemolytic streptococci occurred in a milk dealer who distributed raw milk, and several subsequent cases due to the same serologic type of hemolytic streptococcus occurred among the consumers of his product. His milk, however, had been removed from sale. At this time, Type 1 cases were appearing among persons taking milk from several other local and outlying dealers. Without complete investigation the original situation could have been misleading.

The original purpose of this study was to isolate and classify the hemolytic streptococci from all the cases occurring in the community. For one reason or another, throat cultures could not be obtained in certain cases. Of those cultured, Group A hemolytic streptococci¹² were isolated from 71 or 76 per cent of all the cases occurring in the community. The serologic types of these strains were classified according to Griffith's¹³ slide-agglutination technic. The incidence of the various types is summarized in Table 1. The distribution of types in this community is not unlike that previously reported from certain other Massachusetts communities in 1942-1943⁸ and 1944.¹⁴

The onset of cases by ten-day periods according to serologic type is represented in Figure 1. Cases occurring in 1943 and 1944 are represented schematically. The curve presents two distinct peaks,

*District health officer, Massachusetts Department of Public Health and instructor in epidemiology, Harvard School of Public Health.

†Technical associate in epidemiology, Department of Preventive Medicine, Harvard Medical School, and Department of Epidemiology, Harvard School of Public Health.

each composed of cases due to several different serologic types

CASES IN SCHOOLROOMS

The first case appeared on January 2 in a child who attended Grade 3 of School 1. Type 2 hemo-

TABLE 1 *Distribution of Serologic Types of Hemolytic Streptococci Isolated*

TYPE OF STREPTOCOCCUS	NO. OF CASES	PERCENTAGE
2	25	35
1	22	31
19-24*	10	14
6	7	10
10	4	6
8	2	3
9	1	1
Total	71	

*Cross agglutination with the serums used

lytic streptococci were isolated from this case. Within the next nine days 7 additional cases due to Type 2 appeared among the children in the same schoolroom. Concurrently, on January 4 and 5, 2 cases due to Type 19 hemolytic streptococci developed, and on January 6, 2 cases due to Type 1 also

In contrast to the abrupt outbreak in Grade 3, School 1, cases in the other grades and schools were scattered, sometimes only 1 or 2 cases were reported from a grade or school. Unlike the schoolroom outbreaks previously reported¹⁰ there was no striking correlation between serologic type and schoolroom, primary cases due to different types occurred in the same room, and each type produced secondary cases in the same and other schoolrooms, as well as in nonschool contacts (Table 2).

As would be expected, 71 cases (76 per cent) occurred in children of school or preschool age. The attack rates for scarlet fever in the various schools of the community varied from 0.1 to 16.8 per cent (Table 3). The rate for school children was 5.0 whereas that for preschool children was 3.7 per cent.

Of the 71 cases occurring in school and preschool children, only 38 (54 per cent) could be accounted for by direct case-to-case contact. These contacts, together with extraschool cases secondary to schoolroom cases, are shown in Figure 2.

CASES IN FAMILIES

All cases reported during the period of the study occurred in 49 families. Sixteen families (33 per

FIGURE 1 *Distribution of Cases of Scarlet Fever by Serologic Type*

appeared in this schoolroom. No cases were reported from this schoolroom after January 9.

On January 10 cases began to appear in other grades of the same school and, later in the same month and throughout February, in other schools in the community. Scarlet fever remained prevalent in the other grades of this school and in other schools during the winter and spring months.

cent) accounted for 58 cases (64 per cent). The hemolytic streptococci causing scarlet fever in 14 of these 16 families were classified according to serologic type (Table 4).

As previously observed¹¹ the hemolytic streptococci recovered in the cases occurring in a given family were invariably of the same serologic type, indicating that the secondary cases were the result

of household exposure The intervals between the onset of the primary and secondary cases occurring in these families are shown in Table 5 It is noteworthy that more than a third of the secondary cases occurred more than twenty-one days after the primary case—the usual period of isolation for

scarlet fever due to more than one type of hemolytic streptococci had occurred, multiple infections within a given family were due to a single serologic type This correlation of type with family is in striking contrast with the lack of correlation of type with schoolroom shown in Table 2 Further-

scarlet fever According to our method of determining the interval between cases,* several secondary cases were as long as one hundred and thirty-two days removed from the primary case The role of the family in the spread of scarlet fever is further emphasized by the correlation of

more, the appearance of cases due to a particular serologic type of hemolytic streptococci in a given schoolroom in many cases was shown to be the result of family spread from a child attending some other grade or school

CASES WITH SOURCE ESTABLISHED

It has been reported that the hemolytic streptococci causing illness in a given group are usually of a serologic type not previously present in the population⁴ The heterogeneous type composition of endemic scarlet fever suggests multiple introductions of types previously not present in the community, in contrast to the introduction of a single type producing a well defined outbreak¹ Whether the sudden increase from a single case in 1944 to 9½ cases in the winter and spring of 1945 was due to a more or less general absence of hemolytic streptococci or of particular serologic types in 1944 followed by multiple introductions in 1945 cannot be stated definitely, since carrier rates were not studied Two fairly clear-cut cases were established, however, in which scarlet fever was introduced into the community from outside sources

One patient developed scarlet fever on the evening of the day he arrived home from California Within the next two weeks, three family contacts (2 adults and 1 preschool child) and a next-door neighbor, who came to visit the patient, developed scarlet fever

serologic types of hemolytic streptococci recovered from the primary and secondary cases occurring in a given family irrespective of the schoolroom attended by the patient with the primary case In Table 6 school and nonschool secondary cases are divided according to family and school attended by the patient with the primary case and then arranged according to serologic type Although 1 or more of the children in each family attended schools in which

*In a theoretical family, Cases a, b and c occur Time intervals ab, ac and bc are included in Table 5

All cases were due to Type 2 hemolytic streptococci. The other child in the family who attended school was not ill, and was carrying Type 1 hemolytic streptococci in the throat. Although these cases were due to a type that had already appeared elsewhere in the community, in view of the data on multiple infections in families, there is little doubt

These cases, together with those occurring in schools and families for which a source of infection could be established, comprised 73 per cent of all cases occurring in the community (Table 7). If the 53 cases occurring as multiple infections in 14 families are omitted, however, only 16 (39 per cent) of the remaining cases can be accounted for by

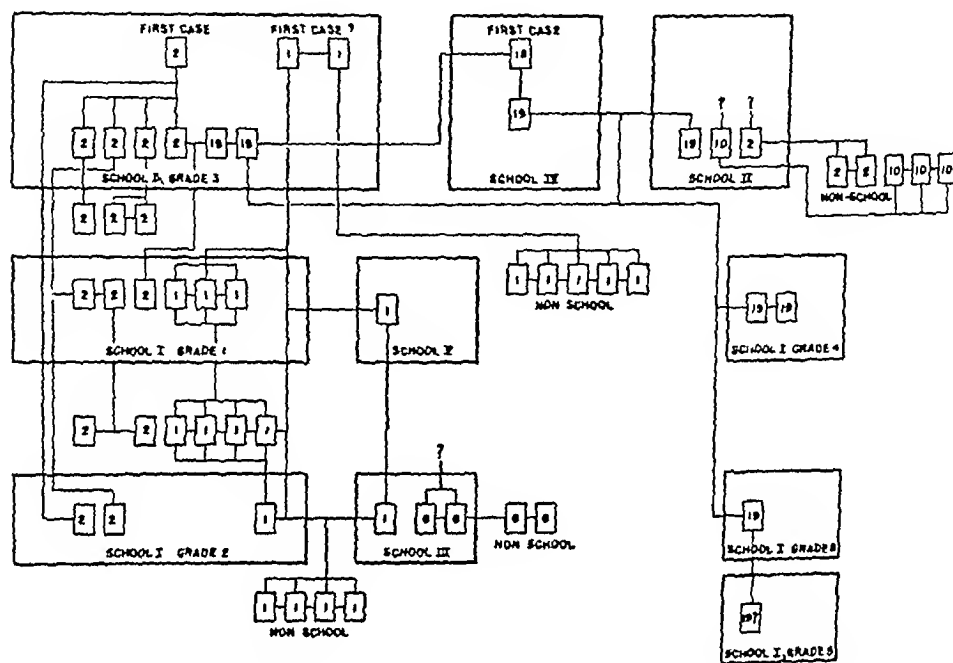

FIGURE 2 Diagrammatic Representation of Spread of Scarlet Fever among School and Preschool Children

that the patient infected his family after he himself had been infected while en route home from California.

Another patient developed scarlet fever on the afternoon of the day he arrived home after several months' absence as a naval recruit. Type 8 hemolytic streptococci were isolated from nose and throat cultures. There was only 1 other case due to this

recognized contact, even with fairly detailed bacteriologic and epidemiologic studies.

DISCUSSION

The role of the schoolroom^{10, 15} and the family unit^{14, 16} in the genesis of scarlet fever, as well as

type, which occurred in a young woman who lived across the hall from the patient. These infections developed late in the spring, near the end of the streptococcus season, otherwise it is conceivable that other cases might have originated from the patient.

in other infectious diseases,¹⁷ is more or less established. The present study seems to be of particular interest in that, although the primary cases appear to have originated in the schoolroom, familial contact was the principal factor in maintaining the spread of the disease. Not only did a few families account for most of the cases occurring in the community but also the appearance of a case due to a given type in a schoolroom could sometimes

accounted for by familial contact with a patient attending another schoolroom. The consistency with which a given type was recovered in all cases occurring in a family indicates that familial contact, rather than chance exposure to the same type of organism outside the home, was usually responsible for spread of infection. This was true not in-

comprising secondary waves were often caused by several serologic types. Since outbreaks of streptococcal infection usually result from the introduction of a type not previously present in the population, the sudden appearance of cases due to three different serologic types in this community suggests multiple introductions of new types

frequently in spite of the fact that the child who contracted scarlet fever attended a schoolroom in which cases due to other serologic types of hemolytic streptococci were occurring.

In several cases only a single case of scarlet fever appeared in a given schoolroom (Fig 2). Since data on the Dick status of the children in these schoolrooms were lacking, it cannot be said that there were available susceptibles. As has been observed, however, the exhaustion of susceptibles is not the sole reason for the cessation of an outbreak of scarlet fever,^{9, 10} and the lack of susceptibles is not the only explanation why an outbreak does not occur or continue to occur in a population unit infected with a suitable strain of hemolytic streptococci. The same phenomenon has been observed in studies of measles,¹⁷ in which the introduction of a case into a population known to contain susceptibles did not give rise to secondary cases. The element of chance is perhaps a factor in such cases, for example, if the patient is exposed only to immune persons before being segregated, no new cases develop. In scarlet fever, furthermore, it is known that all susceptibles (as judged by the Dick test) who acquire the epidemic strain during the course of an outbreak do not develop clinical illness.^{9, 10}

The data presented above differ from the studies by deVaal¹⁵ and our previous experience with scarlet fever in schoolrooms¹⁰ where the majority of cases in a given schoolroom was due to a single serologic type. Griffith¹⁸ observed that although in schools the cases occurring in primary epidemic waves were usually due to a single type, the cases

or else some unknown mechanism. Despite the multiplicity of human contacts complicating the epidemiology of scarlet fever, however, 2 cases were established in which the introduction of disease-producing streptococci into the community from outside sources was followed by secondary cases within the community.

Unlike Griffith's¹⁸ studies the appearance of different serologic types as the cause of disease did

not appear in distinct waves but occurred almost simultaneously (Fig 1), the type composition of each of the peaks of high incidence being essentially the same. The type pattern in this community was not unlike that previously observed in different localities in Massachusetts,^{5, 14} suggesting a fairly widespread distribution of the predominant types producing scarlet fever, and fluctuated only in relatively large units of time and space.

Although it is known that the ability to produce erythrogenic toxin is a characteristic easily acquired or lost,⁵ there is no exact explanation why certain types suddenly appear in a community and attain predominance over other serologic types as a cause of streptococcal disease. Nor is the disappearance

of such a strain from the community clearly understood, for example, there is no adequate explanation for the absence of scarlet fever during 1944 in the community considered, although at the same time the type pattern producing disease in 1945 was present in other Massachusetts communities during 1943-1944.^{5, 14} And there is no satisfactory explanation for the sudden appearance of 94 cases in this community in 1945, with type patterns similar to those previously observed elsewhere.

The succession of seasonal changes appears to be intimately related to the biology of the hemolytic streptococcus, or to its host-parasite relation. The times of high and low incidence of scarlet fever, for example, occur with surprising regularity over a period of several years.¹⁴ Season seems to be a factor common to nearly all outbreaks of streptococcal disease, regardless of type composition, the majority occurring during the winter and early spring months. Griffith's¹⁸ observation that the danger periods of school outbreaks in England are the Christmas and Lent terms applies equally to the observations made in this country. The heterogeneous type composition of endemic scarlet fever, with the parallel seasonal fluctuations in the prevalence of the predominant as well as the sporadic types recorded here and elsewhere,¹⁴ suggests the operation of some factor other than serologic type in the spread of this disease.

SUMMARY

Between January 2 and May 24, 1945, a total of 94 cases of scarlet fever occurred in a community with a population of 6611 as compared with 15 cases reported in 1943 and 1 case in 1944. The hemolytic streptococci isolated from 71 (76 per cent) of these cases were classified according to serologic type. Seven types were encountered. Types 2, 1, 19, 6, 10, 8 and 9 in order of frequency. The type pattern was similar to that previously observed in other Massachusetts communities during the period when the present community was experiencing little scarlet fever.

Seventy-one cases (76 per cent) occurred in children of school and preschool age. The first case appeared in Grade 3 of School 1 and was followed by a sharp outbreak of 11 additional cases in that room. Types 2, 1 and 19 appeared almost simultaneously in this schoolroom. Cases in other rooms of the same school were followed by the appearance of the disease in other schools in the community.

In the entire outbreak 49 families were involved. Of these, 14 contributed 53, or 64 per cent, of all the cases occurring in the community. In each case multiple infections in the same household were due, to the same serologic type. Familial contact accounted for the appearance of sporadic cases in various schools other than those in which the primary cases originated.

There was no correlation between serologic type and schoolroom attended, but there was a correlation between serologic type and family. This suggests that although infection was introduced into the family from the schoolroom, familial contact was the principal factor in maintaining spread.

Other than multiple infections in the same household, a source of infection could be established with the help of serologic classification in only 16 (39 per cent) of the remaining cases.

We acknowledge the assistance of Dr Robert E Archbald, district health officer, Massachusetts Department of Public Health, Dr Frank Collins, chairman, Board of Health, Ipswich, Mr Paul Jodoin, agent, Board of Health Ipswich, and Mrs Jerome Meyer, R.N., School Department, Ipswich.

ACUTE SALPINGITIS DUE TO *FRIEDLÄNDER'S BACILLUS*

Report of a Case

THOMAS W BOTSFORD, M D,* AND THOMAS D KINNEY, M D†

BOSTON

IT is the purpose of this paper to report a case of acute salpingitis in an eighty-year-old woman, caused by *Klebsiella pneumoniae*. Acute suppuration of the fallopian tube in elderly women is rare, and salpingitis due to this organism is doubly unusual. Extrapulmonary *K pneumoniae* infections have received increasing attention in published reports during the last few years. In 1937 Baehr, Schwartzman and Greenspan,¹ reporting a study of 198 cases found only 6 (3.5 per cent) with infection in the vagina, uterus or adnexa. Other cases of Friedländer-bacillus infections of the female genital tract have been reported by Scheyer,² Reichert³ and Hepp.⁴

CASE REPORT

Mrs B H, an 80-year-old widow, entered the Surgical Service of the Peter Bent Brigham Hospital on October 21, 1945, complaining of lower abdominal pain of 6 hours' duration. In 1938 a diagnosis of diverticulosis had been made on barium-enema studies by the family physician. About 6 hours before entry, while riding in a car, the patient experienced a sudden pain just below the umbilicus that quickly shifted to both lower quadrants. The pain was severer on the left than on the right side and was steady in character but was not severe enough to double her up. She was nauseated but did not vomit. She had had a normal bowel movement shortly before the onset of the pain. There had been no changes in bowel habits, and she had noticed no blood or pus in the stools. The bowels had moved once daily with the occasional use of milk of magnesia.

The past history revealed that the patient had undergone a cholecystectomy in 1934 for cholelithiasis. In 1941 she was treated on the Medical Service of the Peter Bent Brigham Hospital for unresolved lobar pneumonia of the right upper lobe. She had subsequently been followed carefully by the family physician, who had examined her sputum on numerous occasions and had found no tubercle bacilli. She had never had hemoptysis and brought up little sputum. In December, 1942, a check-up chest film was reported to show dense fibrous tissue in the right upper lobe with a cavity. Findings were thought to be compatible with an organizing Friedländer-bacillus pneumonia with residual cavity. No Friedländer's bacilli had ever been isolated from the sputum.

There was no family history of typhoid fever, diabetes, tuberculosis, cancer or blood diseases.

Physical examination showed a thin woman lying in bed in no apparent distress. The rectal temperature was 99°F, the pulse 84, and the respirations 26. The blood pressure was 132/82. The chest was clear except for diminished breath sounds over the right upper lobe. The heart was not enlarged, and the sounds were regular and of good quality. The peripheral arteries were firm and tortuous on palpation. The abdomen was moderately distended, and peristalsis was diminished. There was tenderness over the entire lower abdomen but more marked in the left lower quadrant. Involuntary muscular spasm was present in the left lower quadrant, and rebound tenderness was referred. No masses were palpable. Rectal and pelvic examination showed tenderness on the left, but no masses were palpable. The uterus was small, and there was no pain on movement of the cervix.

Examination of the blood showed a hemoglobin of 12.0 gm and a white-cell count of 17,600. The blood smear showed 78 per cent neutrophils, 18 per cent lymphocytes and 4 per cent monocytes. Urinalysis was not remarkable. The blood urea nitrogen was 9 mg., and the plasma protein 6.5 gm per 100 cc., the chloride was 85 milliequiv per liter.

The provisional clinical diagnoses were diverticulitis, with pelvic peritonitis, unresolved pneumonia of the right upper lobe and arteriosclerosis of the peripheral arteries.

The patient was observed for 8 hours, during which a plain film of the abdomen and a chest film were made. The former was essentially negative, and the latter showed extensive pulmonary fibrosis with a cavity in the right upper lobe similar to that reported in the chest film made in 1942. A

FIGURE 1 Low-Power Photomicrograph of Fallopian Tube
Note the diffuseness of the inflammatory reaction

Miller-Abbott tube was passed because of the diminished peristalsis and abdominal distention. At the end of the period of observation the tenderness and spasm in the left lower quadrant had increased, and the temperature had risen to 101.2°F by rectum. The white-cell count rose to 23,000. Because of these changes operation was carried out about 8 hours after entry.

Laparotomy under ether anesthesia was performed through a left-lower-quadrant, rectus-muscle-splitting incision. A moderate amount of thick exudate was present in the pelvis,

*Instructor in surgery, Harvard Medical School, formerly resident in surgery, Peter Bent Brigham Hospital.

†Instructor in pathology, Harvard Medical School, associate pathologist, Peter Bent Brigham Hospital.

and the sigmoid showed numerous diverticulums covered by thick plaques of fibrin. The left fallopian tube overlay the lower sigmoid, and its distal two thirds was markedly swollen and inflamed. The fimbriated end of the tube was attached to the sigmoid, and when it was freed, thick yellow pus escaped. A left salpingectomy and sigmoidostomy were performed, and the wound was closed around the loop of sigmoid without drainage. Cultures of the pelvic exudate and pus from the fallopian tube grew a Type A Friedländer's bacillus. The postoperative diagnoses were acute salpingitis of the left fallopian tube, acute diverticulitis of the sigmoid and pelvic peritonitis.

After operation the course was uneventful. The Miller-Abbott tube was removed on the 3rd postoperative day. The patient was afebrile by the 5th postoperative day. She received 4 gm. of sulfadiazine daily, a blood level between 10 and 15 mg. per 100 cc. being reached. This was discontinued on the 16th postoperative day. The patient was discharged

and serosal layers of the tube to be diffusely infiltrated by polymorphonuclear leukocytes (Fig. 1). The lumen of the tube was distended by exudate made up, for the greater part, of polymorphonuclear leukocytes and containing large numbers of bacteria (Fig. 2). Stains showed these bacteria to be encapsulated, short, gram-negative bacilli.

The fact that Type A strains of Friedländer's bacillus were cultured from the sputum, the pelvic cavity and the fallopian tube is suggestive evidence that the lungs were the portal of entry for the organism in this case. Julianelle,⁶ in a study of eight strains of *K. pneumoniae* gathered from various sources found that 52 per cent were Type A, 15 per cent Type B, 9 per cent Type C and 24 per cent Group X. It is of interest to note that 70 per cent of the Type A strains were associated with pneumonia in human beings. Similarly Perlman and Bullowa⁷ and Solomon⁸ reported series of cases of Friedländer-bacillus pneumonia in which the Type A strains were the infecting organisms in the great majority. Recently Kinney and Ginsberg⁹ stressed the significance of serologic typing of Friedländer's bacillus, and reported 7 cases of liver abscess in which all the organisms except one belonged to other groups than Type A. They further pointed out that Type A, in their experience, was usually associated with respiratory infections. These studies add supportive evidence to the thesis that the patient first suffered from a Friedländer-bacillus pneumonia, and that the tubal infection was metastatic from the lungs.

The sulfonamides have been used in the treatment of *K. pneumoniae* infections with varying results. Heilman¹⁰ reported the use of streptomycin in experimental infections, with encouraging results. Herrell and Nichols¹¹ have stated that they successfully used streptomycin in 45 patients. The patient reported above was treated with sulfadiazine, but the pulmonary infection was unaffected. It must be emphasized that localized infections should be treated surgically in the same fashion as any pyogenic infection. The patient responded well to salpingectomy and drainage of a wound abscess, both associated with a Type A Friedländer's bacillus. She was not given streptomycin, but Herrell and Nichols¹¹ mentioned 4 cases of ozena due to Friedländer's bacillus in which the symptoms were relieved by intramuscular streptomycin in total dosage of 9,600,000 to 14,000,000 units over a period of several days.

SUMMARY

A case of acute salpingitis due to Friedländer's bacillus occurring in an eighty-year-old woman is reported. The patient was treated by salpingectomy with recovery. A Type A Friedländer's bacillus was recovered from the sputum, peritoneal cavity, fallopian tube and a postoperative wound abscess. It is suggested that the lungs were the primary focus of infection. The literature is briefly reviewed.

FIGURE 2 High-Power Photomicrograph of Fallopian Tube
This shows the nature of exudate in the lumen of the tube

on the 20th postoperative day, when the colostomy was functioning well and she was asymptomatic. A check-up 2½ months later showed her to be still doing well. A culture of the colostomy at that time grew no Friedländer's bacilli, but she had developed a small abscess in the operative wound, which was drained. A Type A Friedländer's bacillus was recovered from the culture. The organism was also isolated from the sputum for the first time.

The left fallopian tube measured 7 cm. in length. The diameter of the tube varied from 0.7 to 1.9 cm. The distal two thirds of the tube was swollen and tense, and its serosal surface was dark red and covered by many patches of waxlike fibrinous exudate. The fimbriated portion was ragged and inflamed and covered by exudate. The muscular layers of the tube were swollen. The lumen was patent and was distended by the presence of a large quantity of soft, thick, yellow-white exudate. The mucosa was dull red and ulcerated in places. Microscopic sections showed the muscular, mucosal

THE CAUSE, RELIEF AND PREVENTION OF HEADACHES ARISING FROM CONTACT WITH DYNAMITE

FIRST LIEUTENANT ARTHUR M SCHWARTZ, MC, AUS

AS EARLY as 1910 Laws¹ described the so-called "Nitroglycerin head," and several papers soon followed that helped to elucidate the physiologic effects of nitroglycerin on the human body, especially after the absorption of extremely minute quantities through the unbroken skin, or even the inhalation of the fumes when dynamite is used for blasting purposes.²⁻⁴

Men working in powder plants soon acquire a rather transient immunity to nitroglycerin that can rapidly be lost over a period such as a weekend or during a vacation. Return to the job consequently results in a severe headache, which is also experienced by men first starting to work with dynamite. Such men subsequently discover that the application of a small amount of dynamite within the sweatbands of their hats provides a sufficient immunity to lessen the likelihood of a headache after prolonged contact with dynamite. The headache and its associated symptoms are so severe that it is not unusual for the men to be somewhat irritable, pugnacious and difficult to get along with. A case of homicide has been reported in which a man experiencing a severe dynamite headache drank an alcoholic beverage, which increased the dilatation of the intracerebral vessels and greatly magnified the headache. A display of maniacal manifestations is not unusual.^{5, 6}

With the advent of war it was necessary for many large groups to be exposed to the handling of dynamite and other demolition agents, particularly "C₁." The following report is based on a study conducted at a Pacific combat training center, where considerable quantities of dynamite were dealt with daily to simulate battle conditions and adequately to prepare troops for engagement with the enemy.

Primary interest was in a group of 10 men whose principal duty involved intimate contact with dynamite (20 per cent nitroglycerin), and whose subsequent complaints were intense throbbing headache, nausea, some vomiting and occasional tremors of the upper extremities. Between 8:00 and 11:00 a.m. each man was required to handle several hun-

dred sticks of dynamite. At noon on the same day the 10 men frequently reported to the post dispensary because of intense, severe, debilitating headaches, they wanted something to relieve the throbbing, the tenseness of the scalp, the nausea and the sensation that the top of the head was "ready to blow off."

The problem was approached on the basis of the following considerations: the cause of the headache, the degree of psychogenic element present in its development, possible drugs or combinations of drugs to reduce the severity of the headache once initiated, and prophylaxis to eliminate or diminish the occurrence of the headache.

It is interesting that these men actually dealt with two distinct types of explosives. C₂, a substance closely allied to trinitrotoluol with an oily base, which is molded to fit around such a structure as a pillbox and must be detonated with some form of cap, and dynamite, which contains 20 per cent nitroglycerin and can be exploded by dropping from a suitable height or striking with a heavy object. All men, at one time or another, had witnessed a serious accident from a dynamite explosion involving loss of limb or life — the possible psychogenic factor is obvious. Some form of controlled experiment was required to prove the identity of the offending substance. Patch tests in which dynamite was used and similar ones employing C₂ were prepared. The patch, which contained enough dynamite to cover the surface of a dime, was applied to the back over the left scapula of 15 men reporting for morning sick call, these men, who were told nothing of the nature of the substance applied to their backs, had complained of symptoms in distant, unrelated portions of the body. Fourteen subjects returned three hours later complaining of severe throbbing headaches, associated with a feeling of warmth over the face, and some nausea, and 1 reported the appearance of scintillating bodies in the right visual field. These men were given two aspirin tablets with no relief. In several cases the severity of the symptoms was increased. None of the 15 subjects tested with C₂

complained of headache after the passing of an equal period

What are the mechanisms and the physiologic processes involved in a nitroglycerin headache? Ten subjects who handled dynamite were skin tested with an intradermal injection of 0.01 mg of histamine (0.01 cc of a 1:1000 solution), approximately 90 per cent developed a marked cutaneous reaction, with pseudopodia and much erythema. In fact, this minute quantity was sufficient in one subject to reproduce the headache described under the influence of dynamite. Goodman and Gilman⁷ state that nitroglycerin and nitrites produce an increase in intracranial pressure that is principally due to cerebral vasodilatation, but do not make clear whether the intracerebral or extracerebral vessels are involved. Schumacher and Wolff,⁸ differentiated headaches arising from dilatation of the arteries of the scalp and dura and those due to dilatation of the intracerebral vessels. The histamine headache, which is included in the latter group, is relieved by an increase in the cerebrospinal-fluid pressure effected either by pressor drugs or by direct raising of the pressure. In contrast, the headache that is present in migraine and hypertension and is produced by dilatation of the vessels of the scalp and dura is not affected by an increase in the cerebrospinal-fluid pressure, which merely increases the difficulties when one considers the action of nitroglycerin on the cerebral vessels.

From all available sources and from personal observation it appears that the headache produced by contact with nitroglycerin is closely analogous to that caused by histamine injection. Examination of the fundi at the height of the headache tends to support this claim. The retinal vessels — especially the arteries — of all subjects reveal marked dilatation. With histamine injection a similar vasodilatation of intraocular vessels is observed. All but 1 of the 10 subjects displayed a substantial hypotension, the systolic blood pressure varying between 85 and 110 at the time of the dynamite headache, the normal average systolic pressure for this same group was 119. This lowered arterial pressure is associated with a proportionately reduced spinal-fluid pressure.⁹ Relief of the headache requires a drug with vasoconstricting and pressor effects, which subsequently tends to elevate the cerebrospinal-fluid pressure.

Gottlieb¹⁰ was principally concerned with the vasoconstricting and concomitant pressor action of amphetamine (Benzedrine) sulfate in migraine attacks. In addition, this drug reduces the amplitude of the pulsations of the cranial arteries. As in the migraine syndrome, the headache of nitroglycerin causes extreme fatigue and mental slowness. In many cases adequate performance of simple daily tasks is impossible. Gottlieb administered amphetamine sulfate intravenously and aborted the migraine attack but considered small repeated doses necessary to prevent a recurrence.

A series was set up in which 10 subjects who had never handled dynamite were given amphetamine sulfate orally, 5 mg in the early morning and 10 mg at noon. This schedule was carried out three days before the initial contact with dynamite. The subjects were subsequently given the patch test with dynamite described above. None of the group complained of headache after three hours of continuous exposure to 20 per cent nitroglycerin. Some of the usual side actions of amphetamine were noted including difficulty in falling asleep and a moderate amount of nervousness.

Pelner and Aibel¹¹ obtained gratifying results in 66 patients with periodic and histamine headaches who were given gradually increasing doses of prostigmine bromide orally. Acetylcholine was believed to be a factor in the headache, and desensitization with

FIGURE 1 The Effect of Adrenalin

This graph represents the effect of the injection of 0.5 cc of a 1:1000 adrenalin solution (A) on the average subject with a nitroglycerin headache. The patient experiences immediate relief from the severe headache, but within the passing of a few minutes the symptoms return and in many cases are more pronounced than before the injection.

oral prostigmine bromide was considered possible. The 10 subjects in the series who continuously dealt with dynamite had a common denominator, namely, a marked local cutaneous reaction to intradermal histamine injection. Histamine is a substance with physiologic properties similar to those of acetylcholine. Intradermal injection of either drug produces dilatation of cerebral vessels. Prostigmine, which is an inhibitor of cholinesterase and can mobilize the acetylcholine reserves of the body, lessens the reaction when histamine is released outside tissue cells. One might speculate whether histamine is released in persons in contact with nitroglycerin.

The purpose was to expose the subjects to gradually increasing doses of prostigmine bromide. Forty-five milligrams of the drug was dissolved in 60 cc of water, and the men were instructed to take one drop

n the morning, two at noon and three at night on the first day. An increase of one drop for each dose was ordered until thirty drops had been taken, when thirty drops daily for an entire week, and subsequently thirty drops three times a week, were taken. When the men were receiving thirty drops three times weekly, they were asked to handle dynamite continuously for a full day without the usual precautions, that is, rubber gloves. During the time when they were taking prostigmine bromide the men were not in contact with dynamite. This was necessary to ensure against any transient immunity that might be developed from contact with dynamite. At the completion of a full day's work with dynamite only 20 per cent of the group complained of headache, and this was of a nature that did not require medication for relief.

Early in the study a method of obtaining immediate relief for these men whose assignment brought them in continuous daily contact with dynamite

FIGURE 2 The Effect of Ergotamine Tartrate

This graph represents the immediate and later effects of two injections of 0.25 mg of ergotamine tartrate (A and B), spaced fifteen minutes apart, on the average subject with a nitroglycerin headache.

was sought. A drug with marked vasoconstricting and pressor effects, such as adrenalin, caffeine sodium benzoate, ergotrate, amphetamine sulfate or ergotamine tartrate, appeared to be required. Such analgesics as aspirin, phenacetin, codeine and the barbiturates were without beneficial effect and in many cases increased the severity of the headache and other symptoms. Adrenalin, in a dose of 0.5 cc of a 1:1000 solution, produced transitory relief lasting only several minutes and was soon followed by an increase in the symptoms, possibly owing to the vasodilating effect following vasoconstriction (Fig 1). Ergotrate, in a dosage of 0.2 mg, likewise produced only a momentary obliteration of the headache. After receiving the ergotrate several subjects experienced increased nausea and abdominal cramps—a frequent side action of ergotrate. Ergotamine tartrate,¹² in a dosage of 0.25 mg subcutaneously

was given and produced lasting relief in about 40 per cent of the subjects and a transient effect in 60 per cent (Fig 2). The greatest relief for the headache caused by contact with nitroglycerin was obtained with an intramuscular injection of 0.5 gm of caffeine sodium benzoate, followed by 5 to 10 mg of amphetamine sulfate orally (Fig 3). The systolic blood pressure and the cerebrospinal-fluid pressure rose after a subcutaneous injection of amphetamine sulfate. This is significant because in a nitroglycerin headache there is a reduced arterial pressure and subsequently a reduced spinal-fluid pressure.

FIGURE 3 The Effect of Caffeine Sodium Benzoate followed by Amphetamine Sulfate

This graph represents the effect of the intramuscular injection of 0.5 gm of caffeine sodium benzoate (A), followed in fifteen minutes by the oral ingestion of 5 to 10 mg of amphetamine sulfate (B), on the average subject with a nitroglycerin headache. This combination gave the best results.

sure. About an hour after the ingestion of 10 mg of this drug a moderate rise in the systolic blood pressure, with marked relief of the headache, was observed.

Several laboratory procedures were performed, to give some indication of the physiologic effects of dynamite at the time of the headache. The results of routine blood counts and smears in all subjects were within normal limits. Urine analysis at the height of the headache revealed no glycosuria in any case, in spite of the fact that it has been reported that transient glycosuria occurs in such cases.³ Electrocardiograms were taken at the time of the headache, and in all cases essentially normal tracings were obtained. It was decided to determine accurately whether or not oral prostigmine bromide was desensitizing these men to histamine. The same subjects—those who had marked cutaneous reactions to histamine, as well as those who had been ingesting prostigmine—were given additional skin tests with 0.01 mg of histamine solution. In 90 per cent the severity of the local reaction was markedly reduced. Before oral desensitization with prostigmine bromide, the average

diameter of the wheal produced was 1.3 cm., after desensitization the average diameter was 0.45 cm., a significant reduction.

SUMMARY

The prime factor in the production of headache following contact with dynamite is its 20 per cent content of nitroglycerin, which can be absorbed through the unbroken skin to produce marked symptoms directly related to vasodilatation of the intracerebral vessels.

The psychogenic factor of fear did not play a role in the activation of the headache in subjects who were unaware of the nature of the patch test. It is entirely possible that some psychic element is active in subjects who realize the dangers associated with dynamite handling, but such a factor is not considered significant.

The intramuscular injection of 0.5 gm. of caffeine sodium benzoate followed by oral administration of 5 to 10 mg. of amphetamine sulfate greatly reduced and alleviated the symptoms of headache and within an hour gave lasting relief in over 95 per cent of the subjects.

The administration of 15 mg. of amphetamine sulfate daily for two or three days before exposure completely prevented the occurrence of the headache in all subjects, with minimal side effects.

Daily administration of oral prostigmine bromide in gradually increasing doses protected approxi-

mately 80 per cent of the subjects from the symptoms caused by nitroglycerin contact. It is quite reasonable to assume that desensitization results from a gradual liberation of minute quantities of acetylcholine that shock the intracerebral vessels to dilatation at regular intervals.

TERMINAL ILEITIS WITH OBSTRUCTION AND ABSCESS COMPLICATING PREGNANCY

WILLIAM W. BABSON, M.D.*

GLOUCESTER, MASSACHUSETTS

IT IS the purpose of this paper to report and discuss a patient with cicatrizing ileitis, accompanied by obstruction and abscess, who was observed during the seventh month of pregnancy.

Regional ileitis is the most frequent chronic inflammatory disease of the small bowel and its mesentery. After Crohn¹ directed attention to this disease in 1932, sufficient operative cases had been reported by 1939 to allow Shapiro² to tabulate 519. Its occurrence in a severe form during pregnancy, however, has not been reported in the literature. Intestinal obstruction is also an unusual complication of pregnancy. Hansen,³ in 1941, noted 84 cases recorded in English. Williams⁴ mentions 2 cases in 30,000 deliveries. Slemons and Williams,⁵ in an analysis of types of intestinal obstruction recorded in the world literature, did not mention ileitis as a cause.

Surgical complications—particularly obstruction—in pregnancy should always be considered by the family physician, obstetrician and surgeon, the difficulty of recognizing such complications is well known. Pain is nearly always the prominent symptom. Blakely⁶ stated that the source of pain in pregnancy can be determined if a little care is taken in questioning and investigating the patient. Although pain frequently occurs in pregnancy, it should never be considered lightly, for it is occasionally the result of a serious pathologic state.

The management of acute surgical complications in pregnancy often presents a problem. Authorities are quite well agreed on certain aspects, on others, individual judgment is necessary, and no single rule can be laid down.

It is believed that these facts make the following case worthy of note.

*Surgeon, Addison Gilbert Hospital.

CASE REPORT

A 25-year-old primipara was admitted to an Army Forces regional hospital on April 12, 1945, because of abdominal pain and vomiting during the 7th month of pregnancy. Two months previously the patient had had an episode of diarrhea, vomiting and fever, for which she had been admitted to the obstetric service of this hospital. The symptoms subsided, and she was discharged after 3 hospital days, with a diagnosis of gastroenteritis. On the next evening she had a sudden, severe pain in the right lower quadrant that was steady and nonradiating and gradually decreased in severity. There was local tenderness and discomfort on motion and deep breathing. On the following day a physician stated that the pain was the result of pressure. The patient had subsequently had recurrent, shifting, sharp pain over the entire abdomen, gas pains and often steady pain in the right lower quadrant. The shifting pains were relieved by the passage of flatus or by bowel movements. The appetite was poor, and the patient vomited frequently. At times, when the colicky pains were severe, she could not

appeared to be emaciated. Except for the physical appearance and color, the positive findings were confined to the abdomen, which was enlarged, both from bowel distention and from the enlarged uterus extending 2 fingerbreadths above the umbilicus in keeping with the dates. The uterus lay largely to the left of the midline and during the examination contracted strongly at fairly regular intervals. The fetal heart was heard in the lower left quadrant, and a rate of 140 was noted. In the right lower quadrant a fixed, firm, extremely tender mass was observed close to the anterior iliac spine, approximately 6 by 8 cm in diameter. There was acute tenderness throughout the right side of the abdomen, but there was no referred rebound tenderness. No other organs or other masses could be felt. Peristalsis was intermittent and hyperactive. Rectal examination was not remarkable.

Examination of the blood revealed a red-cell count of 3,250,000, with a hemoglobin of 76 per cent, and a white-cell count of 10,800, with 76 per cent neutrophils. The icteric index was 15. The van den Bergh reaction was 0.5 mg direct, and the serum protein was 6.6 gm per 100 cc. The Rh factor was positive, and the blood Kahn reaction

†One thousand cubic centimeters of 5 per cent glucose in normal saline solution or water is the equivalent of 200 calories, or 50 gm. of glucose.

‡One thousand cubic centimeters of Amigem with 5 per cent glucose is the equivalent of 400 calories or 50 gm of glucose and 50 gm of protein.

retain anything. She was admitted to another hospital 5 weeks later and was discharged after several days' observation, since it was stated that she was improved and presented no evidence of disease. The pain, vomiting and obstipation continued, however, until she re-entered this hospital.

Further questioning revealed that for several months in 1939 the patient considered herself to have colitis. The chief symptoms at that time were frequent loose stools with mucus, there was no blood, abdominal pain or vomiting. The patient continued with her schoolwork. Following this illness, except for a gradual loss of weight, the history was not remarkable until the onset of pregnancy, when difficulty in moving the bowels and ineffectual stools, with some tenesmus, were noted. These symptoms had increased in severity throughout pregnancy. There were also periods of diarrhea accompanied by marked weakness. The patient could remember no tarry or bloody stools. Prior to pregnancy, the appetite, digestion and bowel function had apparently been normal except at the time of the "colitis."

The past history revealed that the patient had never lived in the tropics. There had never been an injury or abdominal operation. The last period had occurred from September 26 to 29, 1944, making the expected date of confinement July 5. The patient had been married for 3 years. The weight in 1936 was 125 pounds, in 1942 115 pounds, in 1944, 102 pounds and at the time of final admission, 98 pounds. The family history was not contributory.

Physical examination on admission revealed a woman who appeared to be severely ill with a chronic disease. The temperature was 98.6°F, the pulse 102, and the respirations 18. The blood pressure was 112/70. There was a slight icteric tinge to the scleras, and the skin was pale and dry. The patient had obviously lost considerable weight and

negative. Examination of the urine was negative. The stools were negative for blood and ova.

Three days after admission a barium enema revealed an extensive lesion of the terminal ileum, with narrowing, fixation and distortion of 31 to 41 cm of bowel. The patient was given 2 whole-blood transfusions, the first being followed by a mild chill and a rise in temperature, — as well as other intensive supportive therapy (Table 1).

On April 17, the patient was transferred to the surgical service, where it was believed that there was an obstructive inflammatory lesion of the terminal ileum. X-ray films revealed passage of barium into what appeared to be a fistula through the bowel wall. The onset of severe pain 2 months before admission was regarded as representing a perforation, and an abscess was believed to be undoubtedly present between bowel loops. Terminal ileitis, tuberculosis, appendiceal abscess and cancer with perforation were considered, the first being the most probable diagnosis. It was believed that surgery was necessary because of the obstruction and the fact that the patient's poor condition precluded expectant treatment. Accordingly a Miller-Abbott tube was passed to relieve obstruction, to decrease the size of the small bowel and give more room at operation, and to relieve pressure on the suture line after operation. The patient was given 0.1 gm of Nembutal 1½ hours before operation, and 8 mg of morphine sulfate and 0.3 mg of scopolamine ½ hour later. Continuous spinal anesthesia was administered as follows: 100 mg of Metycaine at the start of and 25 mg during the operation. Whole blood was administered through a cannula in the ankle vein during operation.

At operation on April 18 an ileotransverse colostomy, with exclusion of the involved terminal ileum by transection of the ileum and closure of the distal end, was performed. A

right vertical abdominal incision was made lateral to the rectus, and the structures were divided in the direction of the wound. Exploration of the peritoneal cavity revealed a large inflammatory adherent mass involving the terminal ileum. In addition several loops of ileum proximal to the mass were densely adherent to each other and to the abdominal wall close to the iliac spine. There was considerable injection of the adjacent peritoneum, and exudate was present between the loops of intestine. Approximately 75 cm of terminal ileum was involved in a typical cicatrizing ileitis with undoubted fistula formation and abscess. The cecum, although somewhat adherent to the mass, was not involved. The ileum was divided between clamps well above the area of the lesion, and the distal end was turned in. The proximal end was anastomosed to the transverse colon, in an end-to-side manner, Young's clamps permitting a closed anastomosis. In the region of the bowel suture and in the wound 6 gm of sulfanilamide crystals were sprinkled. The abdomen was then closed without drainage.

There was considerable cyanosis postoperatively, the result undoubtedly of sulfanilamide in the abdomen. This rapidly cleared in 24 hours. There was marked improvement in the discomfort and pain in the abdomen. There was little nausea, the bowels moved by themselves on the 2nd postoperative day and freely thereafter. The Miller-Abbott tube was removed on the 3rd day. On the 5th day, however, the icterus index had risen to 55. The serum protein had fallen to 4.3 gm per 100 cc in spite of whole-blood transfusions, amino acids and forced protein intake. The urine contained a large amount of albumin and a great deal of bile. It was believed that the jaundice was the result of toxic hepatitis or of other factors, including chronic intestinal disease, acute infection, sulfanilamide and a toxic condition of pregnancy.

The intensive supportive care was continued with adequate fluid, protein and vitamin intake, crude liver extract and progesterone. The daily caloric intake was 2878, which was maintained by food (183 gm of carbohydrate, 131 gm of protein and 74 gm of fat) and by Casec (72 gm of carbohydrate, 158 gm of protein and 36 gm of fat). This was supplemented by intravenous injections, as shown in Table 1.

On the 10th postoperative day the patient went into active labor and delivered a living male infant weighing 3 pounds. The baby, however, survived only a few hours.

On the 14th day the patient complained of a sudden severe pain in the lower abdomen that began in the rectum and spread throughout the abdomen. Examination revealed evidence of spreading peritoneal irritation. The patient was apprehensive and in severe distress. The temperature rose to 101°F, and the pulse to 120, and the blood pressure fell to 100/60. It was apparent that some catastrophe had occurred. Perforation of an abscess and leakage at the suture line were considered. In view of the facts that since operation there had been no evidence of reaction about the anastomotic and transection sites and that the onset of this disturbance was in the pelvis, it was decided that pelvic peritonitis from the inflammatory mass was the likeliest diagnosis. Supportive treatment with blood and penicillin were begun. After several hours the patient improved and localization in the pelvis began to take place. Five days later a pelvic abscess was evacuated through the vagina. From this point on improvement was rapid. The abdominal incision healed by first intention. The patient gained strength rapidly and was discharged from the hospital on June 7.

At the time of a check-up examination on September 20 the patient weighed 110 pounds, felt extremely well, and had an excellent appetite. There was no indigestion or abdominal pain. The bowels moved 3 times daily, the first movement was formed and was followed in a few minutes by 2 small loose dejections. The gas pains, abdominal distress and bowel disturbance, which had been present during pregnancy, had completely disappeared. The periods were normal. Examination disclosed a marked improvement in appearance. Abdominal examination revealed a well healed scar. There was no tenderness or masses. Only slight thickening could be felt in the right iliac fossa. Pelvic examination was negative, as were blood and urine studies. X-ray films disclosed that irregularity and narrowing were still present in the excluded loop of terminal ileum, but repeated plates and fluoroscopy during passage of a barium meal showed no other bowel lesion. The anastomosis functioned well, and there was no tenderness, dilatation or further irregularity.

A final report from the patient on August 1, 1946, indicated that she remained well and weighed 117 pounds.

DISCUSSION

Surgery in ileitis is undertaken for patients with obstruction, fistula or abscess or who are unable to maintain weight and strength with reasonable freedom from symptoms under adequate medical management. Acute nonobstructive lesions in the early stages should not be disturbed, since the etiology is unknown and recurrence is frequent. The exclusion operation, as performed in the case presented above, yielded excellent results in the hands of Garlock and Crohn, who reported 164 cases followed for from two to fourteen years with the low operative mortality of 8.5 per cent.⁷ Resection in one or two stages has been advocated and practiced by many authorities, including Cave⁸ and Bockus.⁹ Marshall,⁹ at the Lahey Clinic, utilized obstructive resection with excellent results.

In the case reported, there was no choice regarding the type of surgical procedure. The involved loop was so completely fixed with inflammatory reaction that resection was completely ruled out. Following the exclusion operation improvement was so marked that further surgery was hardly advisable.

The management of abdominal surgical complications in pregnancy is always an extremely interesting and frequently a difficult problem. Phaneuf¹⁰ and De Lee¹¹ state that in cases in which operation is necessary the pregnancy should be disregarded. If delay is safe, postponement of operation is advisable. In cancer the questions of obstruction, operability and viability must be considered in each case. Occasionally, in intestinal obstruction, hysterectomy is essential, to disclose obstructive points hidden by the uterus.⁴ Cesarean section may be necessary in the true ileus of pregnancy.⁴

In the above case operation to relieve obstruction and to maintain life was urgently needed. It is evident from the pathologic state in the abdomen and the cachectic condition of the patient that an attempt to carry this patient on an expectant regime until viability was assured, with subsequent induction of labor, would have been fraught with grave danger to the mother. Certainly, maintenance of balance of nutrition would have been difficult or impossible for more than a few days without relief of obstruction, even with the aid of intestinal intubation. Accordingly, the pregnancy was ignored, and the short circuiting and exclusion procedure accomplished. Premature labor was almost a certainty, for vigorous contractions, indicating uterine irritability, were present from the time of hospital entry. Slemons and Williams⁵ and Phaneuf¹⁰ state that labor follows in a high percentage of such cases. In intestinal obstruction there is usually a

maternal mortality of 40 per cent and a fetal mortality of 65 per cent

This case illustrates the importance of abdominal pain in pregnancy, as well as the necessity of intensive and continued preoperative and postoperative care because of possible surgical complications and nutritional requirements. Incidental points of interest were the occurrence of jaundice and the rapid drop in serum protein values in the immediate postoperative course in spite of administration of large quantities of protein. The acute hepatitis undoubtedly interfered seriously with protein metabolism.

Continuous spinal anesthesia was probably of considerable value. It permitted a controlled anesthesia, produced by small quantities of drug at intervals, so that reactions could be avoided, excellent relaxation maintained, and time afforded for an accurate, gentle and meticulous procedure.

SUMMARY

A case of obstruction and abscess secondary to terminal ileitis in the seventh month of pregnancy is reported.

The unusual occurrence of severe obstructive ileitis in pregnancy is noted.

Certain aspects of the surgical management of the patient are briefly discussed.

CYSTS, HYPERPLASIAS AND PAPILLOMAS

The greatest difficulty in interpretation and classification is encountered in lesions that exhibit cysts, hyperplasias or papillomatous formation. The lesions frequently coexist with or are superimposed on the abnormalities described above. Thus it can be seen that the opportunity to designate some lesions as distinct entities is relatively rare. It is probable that the various changes are manifestations of the same syndrome, but the evidence is not conclusive. The lesions usually occur in women in the latter part of active sexual life. Unlike the syndromes described above, regression following the menopause appears to be less frequent, but this cannot be stated with certainty since observations are based entirely on patients who consult a physician. Cyclic swelling and objective symptoms other than the presence of isolated or diffuse lumpiness of the breast are conspicuously absent. The syndromes seem to occur more frequently in childless women, and coexistent pelvic disease is not unusual.⁸ The physical findings vary considerably and are difficult to define in many cases. For the purpose of clarification the lesions are described on the basis of the dominant histologic findings, even though other changes are found elsewhere in the breast.

Macroscopic Cysts

The solitary cyst or multiple cyst of similar origin and the so-called "blue dome" cyst of Bloodgood and others are easily distinguished. As Foote and Stewart¹³ pointed out, the lesions designated under this heading should be included only if they are isolated structures—that is, visible to the naked eye (1 mm. or more in size)—and distended with fluid and totally separate from the duct and lobule systems. It is further stressed that a diagnosis of microscopic cysts requires serial sections to prove complete isolation and loss of communication with the adjacent ducts or lobules. Lesions often appear cystic but are actually dilatation of the duct system or acini. Macroscopic cysts vary considerably in size, and if large enough, are tense to palpation. Epithelial linings are frequently absent, and hyperplasia is rarely found, even when the linings can be distinguished. Intracystic papillomas

and carcinomas are unusual.¹³ As a rule, lesions that appear to arise in cysts must be considered intraductal unless proved otherwise by serial section.

Hyperplasias

Epithelial hyperplasia in the duct systems and acini may occur with or without cysts. The degree of the proliferative process varies considerably in the same breast and may be palpated as a localized nodularity or as a diffuse process, usually of "doughy" consistence and with associated areas of irregular nodularity. Dilatation associated with blockage of the duct or lobule component by the proliferative lesion may resemble true cysts. Secretion, either serous or serosanguinous, may occur. These lesions resemble those originally described by Reclus.³¹

Papillomas

There is no sharp distinction between the simple hyperplasias and the more marked types resembling and tending to papillomatous formation. Frequently all stages of hyperplasia are seen in the same breast, and at times an apparent transition to papillomatous formation can be distinguished. For this reason many observers are of the opinion that these lesions are advanced stages of the simpler processes. Thus, a division based on the degree of hyperplasia must be arbitrary. Included under the designation of papillomas are the obvious and gross papillary lesions, with a definite stalk found in the larger duct systems, and microscopic lesions involving the smaller duct systems manifested by marked epithelial hyperplasia with papillomatous features and without obvious evidence of a stalk. Various degrees of papillomatous change are seen in the same breast, and may be associated with macroscopic cysts or duct or acinar dilatation or both.

The gross papilloma, which may be multiple, usually appears near the duct opening in the region of the areola and, although infrequently palpated, can sometimes be detected by transillumination and gross thickening of the proximal duct system involved and by mammography. Discharge from the involved duct is often seen and is usually serosanguinous in contrast to the fluid noted in other lesions. Occasionally the ducts containing gross papillomas can be identified by systematic palpation around the areola and by application of pressure at various points to elicit a discharge.

Microscopic papillomas are almost invariably found elsewhere in the breast in the presence of a

oss papilloma Physical findings, although sometimes more pronounced, are essentially the same as those observed in breasts with only epithelial hyperplasia. The syndrome is consistent with that described by Schimmelbusch.²²

Other Lesions

Foote and Stewart¹³ have described and introduced new terms for several other lesions that appear to be distinctive. Although, as they point out, such terms may be undesirable, it is believed that such terminology should be encouraged, inasmuch as it stimulates interest and demands more specific interpretations of lesions that are frequently seen but poorly understood. These terms include the following:

Blunt duct adenosis In this manifestation, the duct ends abruptly near its distal portion without termination in lobules. The lumens are usually narrow, and the epithelial lining varies from simple hyperplasia to that resembling papillomas in the earlier stages. The advanced stages are characterized by dilatation and flattening of the epithelium. All degrees of change may be seen in a single breast. The process may exist as a single focus or as a palpable mass of nodularity, especially when lobules are absent and small cysts possibly arising as an end result of blunt duct adenosis are numerous.

Aprocrine epithelium Large, tall, cylindrical cells possessing relatively small nuclei and abundant, bright eosinophilic cytoplasm are characteristic of aprocrine epithelium, aggregates of which grossly present a discrete yellowish-brown appearance of slightly elevated, glistening areas, small in diameter, larger aggregates may be cystic as well.

Sclerosing adenosis This abnormality may be manifested as an early florid phase, characterized by epithelial proliferation, an intermediate phase and a late phase in which fibrous elements are dominant. It may appear as a grossly localized mass or more frequently as focal areas seen only on histologic examination. The lesions usually arise in terminal ducts or lobules.

Lobular alteration Primary and secondary types have been distinguished. For a complete discussion one is referred to the original study.¹³ In primary lobular alteration, as a rule, there is homogeneity of structures. The following three types, which are similar to adenofibrosis, are usually seen: a small number of lobules condensed with small, scanty acini and fibrous stroma often replaced by fat, an average number and size of lobules, with abundant, loose and edematous connective tissue and few but large and piled up epithelial components, and an irregular—that is, heterogeneous—lobule pattern that in some cases exhibits epithelial activity and in others appears to be undergoing regression,

with evidence of atrophy and cystic formation. In secondary lobular alteration, lobules adjacent to a mass—such as cysts, fibroadenomas and cancer—exhibit interlobular edema, changes in contour and size, epithelial components and round-cell infiltration, as the primary lesions progress or persist, however, all degrees of change are noted until the lobules are obliterated, edema disappears and round-cell infiltration is predominant.

Objective evidences of these newly designated microscopic lesions are difficult to define. By correlation of clinical and histologic observations, however, it is likely that they will be clarified.

It is necessary to emphasize again that the lesions discussed under the term “chronic cystic mastitis” are not necessarily separate entities, but may coexist in any combination to complete the general picture.

RELATION OF BENIGN LESIONS TO CARCINOMA

This problem has been discussed elsewhere,^{3, 13, 23-30} but the increasing statistical and histologic observations warrant additional evaluation. It is becoming increasingly apparent that certain lesions are apt to be associated with or to precede cancer of the breast whereas others are equivocal or may be of no significance. The more thorough studies indicate that adenofibrosis,²⁹ fibroadenomas^{13, 29} and macroscopic cysts¹³ are less often seen in conjunction with cancer of the breast. Other lesions included under chronic cystic mastitis are more difficult to evaluate. These manifestations, which have a greater tendency to be associated with carcinoma, are marked epithelial hyperplasia,²⁹ papillomatosis^{13, 29} and, possibly, blunt duct adenosis.¹³ As pointed out by several observers, the papillomatous lesions, especially when atypical, precede or coexist more frequently with carcinoma.^{13, 29} In some cases transition from the benign state to the neoplastic process can be demonstrated.¹³ An appraisal of the situation with a broad point of view indicates that any of the abnormalities alluded to—with the possible exception of fibroadenoma—may precede or coexist with malignant change in the breast. Some are obviously of a special significance, but as yet they cannot be defined with certainty. For the moment the question is still open, but it is expected that studies will continue to elucidate this fundamental problem.

BENIGN BREAST DISEASE IN THE MALE

As in the female, certain benign disease of the male breast is erroneously designated mastitis. The term mastitis should be used only for specific inflammatory processes that are rare and apparently bear no relation to the lesions usually seen in the male. Gynecomastia is also used by some observers as a general term to describe the common forms of benign breast disease in the male, but it should be reserved for a special group as pointed out below. For these reasons, the term “mammoplasia” is

suggested to describe the benign noninflammatory processes, which are transient in character and as such are distinguished from gynecomastia. It is realized that introduction of another term into an already confused field may be undesirable, but it is believed justifiable in view of advances made in the concepts of breast disease in general.

Adolescent or Pubertal Mammoplastia

This condition, which in the male is akin to the changes seen normally at the onset of breast development in the female, usually appears between the twelfth and seventeenth years and is characterized by the presence of a well defined, freely movable, discoid mass beneath and closely associated with the areola. The mass varies in size from less than 1 to 5 cm., but as a rule is 2 or 3 cm. The nipple and areola may also be increased in size. The process is usually unilateral at the onset, but may affect both breasts, simultaneously or successively.³³ It occurs more frequently than is generally recognized. Jung and Shafton⁶ in approximately a thousand examinations found that it was an integral part of the process of puberty. It is not seen oftener because of the frequently transient character of the process, which may arise and regress within even a month. Histologic examination reveals lengthening and hypertrophy of the ducts, with an increase in periductal connective tissue. Lobule formation is usually absent. In a small percentage of cases this lesion persists and may then be correctly called gynecomastia. A process similar to adolescent mammoplastia is seen in postadolescent males. A number of cases were reported in soldiers in World War II. Few, if any, had a history of previous breast trouble so that the process may well be similar to that noted in the adolescent.

Gynecomastia

In gynecomastia the contour and elements of the breast approach those of the normal woman. As stated above the abnormality may represent a persistence of the adolescent type or may arise spontaneously in the adult or in the presence of associated diseases. It may be unilateral or bilateral. Histologically, in addition to the changes described above, there may be hyperplasia of the duct epithelium, dilatation of the ducts and occasional secretion. The presence of acini and lobules is rare. The main differences from the other types of benign breast disease in the male are the persistence and the physical characteristics.

Senescent Mammoplastia

After the age of forty-five years, but particularly after sixty, changes resembling those seen at puberty are frequently encountered. Some, of course, occur earlier. The disease behaves in a fashion similar to that seen in the youth, but spontaneous regression is not so frequent.

Etiologic Factors

There are no obvious associated abnormalities in the large majority of these cases. Adolescent and senescent mammoplastia, as noted, occur at the extremes of active sexual life. It is possible, therefore, that at these periods there is a temporary hormonal imbalance. Both mammoplastia and gynecomastia, however, occur in association with other diseases and in such cases possible etiologic factors are apparent. These may be described as follows.

Atrophy of the testicle following orchitis or injury

The spermatic tubules are frequently atrophic and the atrophy thus accompanied by a relative or actual increase in the interstitial cells. Since these cells are supposedly the site of origin of androgens, it is possible that they are responsible for the change in the breast.

Neoplasms of the testes Mammoplastia and gynecomastia are sometimes associated with tumors of the testes, particularly chorioepithelioma. Gilbert³⁴ is of the opinion that the breast lesions are of two types — a "physiologic," resembling the usual mammoplastia in males and not necessarily related directly to the tumor of the testes, and a "choriogenic," most frequently related to the chorioepithelioma and resembling the female breast in its histologic characteristics, especially during pregnancy. The pituitary gland in cases with choriogenic gynecomastia shows changes that are also seen in pregnancy. In contrast to the physiologic type, these lesions may be caused by the hormones secreted by the tumor itself. Several cases of gynecomastia have also been associated with interstitial-cell tumors of the testes.³⁵ The nature of the stimulus in these cases is not clear, for although one would expect the androgens to be in excess, 1 patient had loss of libido suggesting destruction of testicular function and failure of the tumor to secrete a hormone to maintain such a function.

Functioning tumors of adrenal cortex These tumors may produce feminization, in contrast to the usual masculinizing syndrome seen in females and prepubertal males.^{36, 37} The syndrome is characterized by mammary enlargement, regression of secondary sex characters and atrophy of the testes. Since estrogens as well as androgens have been recovered from the adrenal gland and because elevated excretion levels of both these substances are frequently found in patients with adrenocortical tumors, a hormonal cause seems evident, especially since removal of the tumor is followed by regression of the breast lesion.

*Hypophyseal adenoma*³⁸ These lesions may give rise to atypical pituitary secretion affecting the breast directly or indirectly as a result of stimulation of the peripheral endocrine organs.

Cirrhosis of liver Breast changes associated with cirrhosis are sometimes encountered.³⁹ The

patients often show testicular atrophy. It is conceivable that the breast lesions may be caused by faulty metabolism of the hormones as a result of liver cirrhosis, since the liver is intimately concerned with such a metabolism. An alternative possibility is a loss of testicular function.

Syndrome of unknown cause A syndrome characterized by aspermatogenesis, testicular atrophy and gynecomastia without known cause has been reported by Klinefelter and co-workers.⁴⁰ The testicular changes resembled those seen after orchitis or injury, and may possibly fall into the same category.

Other conditions The mechanism involved in the production of mammoplasia in patients with thyrotoxicosis,⁴¹ leukemia and pulmonary carcinoma, as well as in soldiers with malnutrition or debilitating diseases,⁴² is not clear. It seems, however, that in these diseases there is also a disturbance of the metabolism of the hormones.

Hormonal induction Mammoplasia of a transient character develops in eunuchs following the injection of testosterone.⁴³⁻⁴⁴ Such treatment is followed by an increased excretion of estrogens in the urine and suggests, therefore, a metabolism or conversion of the androgens to estrogenic substances.⁴⁵⁻⁴⁷ This may be characteristic for the eunuch, since such changes after administration of androgens to a normal person are exceedingly rare. As would be expected the administration of estrogens to the male for various causes — especially carcinomas of the prostate gland — results in mammary hypertrophy.⁴⁸⁻⁵¹ The nipples and areola enlarge, and in some cases there is marked epithelial proliferation and acinar formation. Interestingly enough, I have observed unilateral or asymmetrical response after estrogen therapy. Such a finding is consistent with the concept of differential tissue sensitivity. Removal of the stimulus results in relatively rapid regression of the process. Excretion studies of gonadotropic and sex hormones in the urine have been fully described elsewhere.³

Benign breast disease in the male seems to be associated with an endocrine imbalance, either as a result of sexual metamorphosis or of an associated abnormality or tumor. Since the changes normally produced by the various hormones are not identical, clarification may come when a careful correlation is made between the histologic appearance of the breast and a known activating agent. A common denominator may be found in the so-called "mammogenic hormones,"⁵² which may be activated by either estrogens or androgens. Hence, similar lesions could be produced by these different hormones. Most of the available data point to the estrogens as an important factor. Changes induced in the breast by the administration of estrogens are frequently seen, but except in the eunuch testosterone seldom pro-

duces obvious breast abnormalities. Moreover, testosterone has been used with success in the treatment of the more transient types of mammoplasia. These paradoxical findings may possibly be explained by a difference in the metabolism of the hormones as a result of disease or variation in the endocrine status.

DISCUSSION

The available clinical and experimental information emphasizes the significance of the endocrine system in the development and growth of the mammary gland. The ovary and hypophysis are especially important, for without one or the other breast development does not occur or ceases entirely. Furthermore, removal of these organs leads to regressive changes in the fully developed breast. Thus, it has been contended that disease of the breast is definitely related to or caused by alterations of function or secretion of certain glands of internal secretion. Factual data, for such a thesis, have been reviewed elsewhere.² A general discussion of the possibilities involved seems necessary, however, since certain factors are common to all types of breast disease.

Factors other than endocrine must be considered in the development of breast disease. Chief among these are heredity, race, color and constitutional type, which are frequently interrelated but may be individually of special significance. Although the evidence to support these possibilities is far from conclusive, one may justifiably speculate on them. Physiologic status, endocrine metabolism and secretion and susceptibility to the disease may depend to a considerable degree on these fundamental backgrounds. These basic states in some measure may thus determine the type and degree of response of the organism to normal or superimposed stimuli. This would help to explain the variety of changes in the breast that have been attributed to the same agent, such as estrogens.

The stage of life and state of the breast when abnormalities appear may also determine the type and degree of response to a given stimulus. It has been shown that the histologic structure and clinical manifestations of diseases that arise during various age periods vary considerably. Moreover, the degree of development and structure of the breast may differ regardless of age as a result of variations in physiologic status. Dieckmann⁵ has shown that the extent of development of the breast, particularly at puberty, is subject to wide variation among different persons. Previous pregnancies and normal and abnormal lactation account for breast changes not encountered in the virgin female. Other processes, such as inflammatory disease, may likewise alter the state of the breast. Thus, the breast may exhibit wide varieties of histologic structure under different conditions, and these dissimilar substrates may therefore vary considerably in their response to a

single stimulus and may determine to some degree the abnormal changes that subsequently appear

Foremost among the probable stimuli responsible for breast disease are those of the endocrine and nervous systems. The hormones that have been the subject of the most intensive study are the estrogens. Nevertheless, the possibilities suggested by investigations may apply to other hormones as well. How may estrogens produce these atypical states? Several possible modes of action seem tenable. Physiologic amounts of the hormone may act on tissue that is more sensitive than normal. This susceptibility may be related to the metabolic status of the host, to special characteristics of the cells, or to a change in the breast as a result of the activity of other agents. It has been demonstrated that estrogens are destroyed by the liver. Normal quantities of the hormone may be secreted, but because of defective function of the liver, abnormal quantities may be released to the tissues. Excessive quantities of the hormone may be responsible, but, except in cancer-susceptible animals, the effects are limited. Atypical hormones with carcinogenic activity may be produced. This is possible since the steroid hormones are closely allied to several of the known synthetic carcinogens. It is conceivable that the formation of carcinogenic agents from hormones may occur as a result of a faulty metabolism due to a change in the physiologic state of the host. Lack of a hormone, which normally stimulates the breast, may lead to degenerative or regressive changes that may then allow other agents to act.

As has been pointed out, the nervous system may also be involved. The action may be direct, but it is more probable that such stimuli exert their effect by causing excesses or alterations of hormonal secretion. Furthermore, the close interrelation of the various endocrine organs suggests that disturbance of one organ could affect the function of the others. Because of the possible methods of action or alterations of hormonal secretion, there is still lack of conclusive evidence to justify the acceptance of any one factor.

As suggested above, the state of the breast at the time that an abnormal stimulation is superimposed is probably of some importance. Infantile and virginal hypertrophy, early ripening, adenofibrosis, fibroadenomas in the female and gynecomastia and mammoplasia in the male are remarkably similar in histologic appearance and in their resemblance to changes usually seen in the normal adolescent female. It is conceivable, therefore, that they may be due to the same etiologic agent, possibly the hormones. Lewis and Geschickter²¹ emphasized this similarity in virginal hypertrophy, gynecomastia and fibroadenoma, and there is fairly good evidence to support such an opinion. The different forms of disease classified under the present accepted designation of "chronic cystic mastitis" also basically

resemble each other, in spite of considerable variation in the individual case.

It has repeatedly been stressed that lesions described above as possible entities may coexist in the same breast. This suggests that each type may represent a later stage of or may be superimposed on the same basic abnormality. The changes may represent manifestations of quiescence or stimulation as indicated by involutions or proliferations that in part may have occurred prior to the time of examination. Thus, this point of view reverts to the thesis that localized areas of the specific tissue are unusually sensitive to a stimulus. It is my opinion that this sensitivity is a major determining factor in the production of the heterogeneous groups of lesions described.

In almost all types of breast disease—from the simple infantile hypertrophy to complex breast cancer—there is a suggestion of some dysfunction of the endocrine system in many cases. Nevertheless, it can be stated that evidence is insufficient to support the thesis that the hormones themselves are directly responsible for the production of benign and malignant lesions. It is possible, however, that they may be exciting factors or may prepare a suitable substrate and thus contribute to the initiation and production of the varieties of breast disease.

As a result of increasing knowledge and clarification of lesions of the breast, concepts have changed in the last decade regarding management of benign disease. A solitary mass or a localized nodularity, as has been repeatedly emphasized in all teachings on breast disease, must be investigated surgically, since it is often impossible to distinguish between clinically benign lesions and early cancer. Obviously, radical mastectomy must be performed if the lesion proves to be cancer. The removal of a localized benign process may be all that is necessary, particularly in young women. Thereafter, systematic observation should be instituted.

Benign lesions except for the so-called "precancerous hyperplasias" are of significance so far as they cause annoying symptoms or exert an unfavorable psychologic effect on the patient. It is the responsibility of the physician to decide on the proper management in the individual case. This demands, therefore, an objective view based on a broad comprehension of breast disease. Since many of the lesions are diffuse one is faced with the choice of conservative management or a simple mastectomy, if the indications warrant it, as a preventive measure against cancer. The majority of benign diffuse processes frequently involve both breasts, and it therefore seems illogical to perform unilateral simple mastectomy as a prophylaxis against cancer. Warren²² states that if an excised focus of chronic cystic mastitis shows evidence of definite precancerous hyperplasia, a simple mastectomy should be performed. He believes, however, that there is not sufficient risk of subsequent develop-

ent of carcinoma in the remaining breast to warrant or justify bilateral mastectomy as a rule. It is by conviction that simple mastectomy is performed so frequently for benign lesions of the breast.

Conservative management and reassurance is all that is necessary in handling the syndromes of adenosis and nonpuerperal secretion, in the absence of a localized mass. So far as cystic disease is concerned, the process is often diffuse. It is not unusual to find additional cysts arising after a solitary lesion has been removed surgically. The surgeon is therefore faced with the problem of another or repeated excisions, simple mastectomy or conservative management.

Solitary large cysts may be aspirated with considerable safety, since the possibility of cancer within the lesions described is relatively remote. As a rule, however, these lesions recur, and surgical intervention is necessary for eradication. If multiple cysts are found and the diagnosis is verified by aspiration or local excision of a typical lesion, careful observation in a majority of cases will accomplish the same effect in the end as a radical procedure. In young women particularly the psychologic effect of simple mastectomy may be profound, in older women there is less emotional reaction to the procedure.

When one is faced with the more complex structures—particularly those of precancerous hyperplasia or papillomatous change—the problem becomes increasingly difficult. In the single gross papilloma, excision of the entire duct system may be all that is necessary. The gross lesions may be multiple, however, so that every effort should be made to identify them. If the papillomatous process is diffuse or atypical or if precancerous hyperplasias exist, it is probably wiser to carry out simple mastectomy as a prophylactic measure because of apparently close association with cancer.

CONCLUSIONS

The endocrine organs and their secretions are necessary for normal growth, development and maintenance of the mammary gland. As such, they are indirectly responsible for breast disease, since they provide the tissue in which the lesions arise.

Factors such as heredity, constitution, race, color and physiologic state of the patient must also be considered causes of breast disease.

The state of the breast at the time of onset of disease seems to be an important factor in the type

of lesion seen. A single stimulus may thus produce a variety of apparently different lesions.

Localized tissue susceptibility may account for an unusual response to an apparent normal stimulus.

Endocrine dysfunction is frequently associated with and may be responsible for certain benign lesions, but there is no absolute proof that it is the only or direct etiologic factor.

A number of histologic lesions classified under the general term of chronic cystic mastitis may be distinct entities, but they frequently coexist in the same breast.

A revised classification of breast lesions and a recognition of these as distinct entities is essential to a better understanding of etiologic factors and to intelligent management of the individual case.

CASE 32411

PRESENTATION OF CASE

A sixty-nine-year-old unemployed woman, formerly a practical nurse, entered the hospital because of palpitation.

The patient had been in good health until two and a half years before admission, when she first noted shortness of breath and palpitation after mild exertion. From then on exertional dyspnea progressed steadily until she was unable to do more than walk about her room without precipitating an attack. During the same interval, orthopnea developed and there were occasional attacks of nocturnal dyspnea, usually of no more than fifteen minutes' duration. Palpitation was always a prominent symptom, occurring at first only following exertion but later during bed rest. For six months there had been a constant, increasing coarse tremor of both hands and arms. Slight numbness and tingling of the fingers had appeared during the previous two months. Nocturia (two or three times) and frequency during the day appeared in the course of the illness. There was never any swelling of the hands, face, abdomen or ankles, or any precordial pain, oppression or convulsive seizures. Three days before admission the patient fainted, falling across the bed. Several minutes after she regained consciousness there was a spontaneous brisk nosebleed, which lasted several minutes. She noticed no visual changes or muscular weakness on recovery. She had never had hypertension. During the two and a half years of illness there had been progressive anorexia, accompanied by a 55-pound weight loss. Muscular weakness was a prominent symptom.

For three months after the onset of the symptoms the patient had been given digitalis by a physician but had subsequently received none. For two years she had received weekly injections of liver and many iron tablets. Three months before admission 20 drops of iodine solution was administered three times daily, and the patient thought that she felt stronger for a time.

As a child the patient had had aches first in one knee and then in the other that lasted several days. The joints were not swollen, and she was not put to bed.

Physical examination revealed a thin, pale woman exhibiting a marked coarse tremor of the hands and lips. The face bore a masklike expression. The skin was dry and warm. The arms and legs were wasted and weak. There was slight exophthalmos, lid lag and infrequent blinking. The thyroid gland was slightly enlarged and nodular. A Grade III systolic and a harsh mid-diastolic murmur were heard at the apex, and there was a Grade II or III systolic murmur in the aortic area. Flatness, decreased breath sounds and decreased tactile fremitus were elicited at the left lung base. The liver edge was palpable three fingerbreadths below the costal margin. The tremor of the hands was more marked on intention. Pelvic examination revealed tenderness in both vaults, no masses were palpable. There was tenderness over the lumbar spine and sacrum.

The temperature was 98.0°F, the pulse 95, and the respirations 20. The blood pressure was 110 systolic, 58 diastolic.

Examination of the blood showed a red-cell count of 1,890,000, with a hemoglobin of 67 gm, and a white-cell count of 11,800, with 94 per cent neutrophils. The hematocrit was 19 per cent. The non-protein nitrogen was 140 mg, the total protein 7.2 gm, with a normal albumin-globulin ratio, the blood sugar 108 mg, and the calcium 9.6 mg per 100 cc. The basal metabolic rate was +11 per cent. The specific gravity of the urine was 1.006, and there was a + albumin reaction, the sediment contained 3 white cells and 1 epithelial cell per high-power field. A stool was brown and gave a ++++ guaiac test.

On x-ray examination the heart appeared enlarged on both sides and also in the anteroposterior diameter. The aorta was extensively calcified from the arch to the iliac arteries. The left pleural cavity contained a moderate amount of fluid, and there was a small amount on the right. An electrocardiogram showed inverted T₁, T_{CR1}, and T_{CR2}, prominent S₂, upright T₂, T₃, and T_{CR3}, and depressed ST_{CR1} and ST_{CR2}. The rhythm was normal.

The patient was slightly short of breath, slightly orthopneic and extremely weak but had no specific complaints. Barium studies of the upper gastrointestinal tract showed the esophagus displaced to the right and posteriorly, apparently by the left auricle (Fig. 1). The stomach and duodenum were normal except for a pressure defect produced in the latter by the gall bladder. The severe anemia did not improve. White cells up to 20 per high-power field appeared in the urine, which was otherwise unchanged.

On the fourth hospital day the patient suddenly sat up in bed and expired.

DIFFERENTIAL DIAGNOSIS

DR. RULON W. RAWSON: May we see the x-ray films?

DR. JAMES R. LINGLEY The heart shows marked generalized enlargement, without characteristic configuration. The lung fields are clear, but there is fluid at both bases, more marked on the left than on the right. The esophagus is displaced, as described in the record, apparently by this enlarged left auricle. I think that that goes along with the general cardiac enlargement. On this lateral view there is also a ring of calcification in the heart, which corre-

thought to be an enlarged left auricle, makes the diagnosis almost certain. The aortic systolic murmur can be explained by rheumatic heart disease, but can likewise be explained by arteriosclerosis and the calcified aorta that Dr. Lingley has shown us.

Dr. Bland tells me that the electrocardiographic changes are consistent with coronary heart disease and some old infarction but states also that it could be explained on the basis of anemia. The finding of

FIGURE 1 Lateral Chest Film, Showing Generalized Aortic Calcification, Calcification of Mitral Annulus and Pressure Displacement of Esophagus by Left Auricle

sponds to the annulus of the mitral valve. There is an extreme degree of calcification in the aorta, apparently it extends the entire length from the heart to the bifurcation.

DR. RAWSON It is impossible for me to ascribe this entire picture to one disease entity. The diagnosis of old rheumatic heart disease seems a sure bet. The history of the joint pains in childhood suggests it, and the Grade III systolic and the mid-diastolic murmurs at the apex are also suggestive of that. The x-ray finding of enlargement of the heart on both sides in the anteroposterior diameter, with displacement of the esophagus to the right by what was

fluid in the chest can be adequately accounted for on the basis of cardiac failure, as can the enlargement of the liver, although enlargement of the liver could also be explained by some other diagnostic possibilities, which I shall discuss.

In view of the weight loss, the tremor, the palpitation, the lid lag, the exophthalmos, the warm skin and the symptomatic improvement following the administration of iodine one has to think of Graves's disease. The weight loss can be explained on the basis of anorexia. The tremor was a coarse one. As a rule the tremor in Graves's disease is fine and rapid. Frequently in older people we do see a

coarse tremor, which is rapid, however. There is no statement whether or not this tremor was rapid. I should prefer to attribute it to weakness. The palpitation could also be explained on the basis of thyrotoxicosis, but I think that it is adequately accounted for on the basis of heart disease and the anemia. Enlarged liver does occur with long untreated Graves's disease, but again is adequately explained on the basis of heart failure. The eye signs, the goiter and the subjective improvement on the administration of iodine are strongly suggestive of Graves's disease. The basal metabolic rate, however, was only +11 per cent, which is quite low for a patient this ill with thyrotoxicosis, especially in the presence of heart failure. Usually patients with heart failure have elevated basal metabolic rates, whether or not they have thyroid disease. It is of interest that a number of years ago in an analysis of patients in this hospital who had heart disease and on whom total thyroidectomies were done, it was found that frequently when they returned to the hospital or clinic in a state of decompensation the basal metabolic rate was elevated as high as +20 to +25 per cent, and that when compensation was restored and the fluid removed, the basal metabolic rate fell to -20 per cent or lower. So I am skeptical of the diagnosis of Graves's disease with a basal metabolic rate of only +11 per cent, especially with cardiac decompensation. We have seen a few patients, however, who entered the hospital with thyroid storm and who were so debilitated that had we been able to determine the basal metabolic rates, it is possible that they would have been found low. It should be pointed out that neither the cardiac failure, the decompensation nor the hyperthyroidism can account for this degree of anemia. Also, it is important to recognize that the white-cell count of 11,800, with 94 per cent neutrophils, is not a classic picture for Graves's disease. Usually there are leukopenia and lymphocytosis.

The anemia was hyperchromic. The color index was 1.25, with a mean corpuscular volume of 1, and therefore one should consider the diagnosis of pernicious anemia. The anorexia for two and a half years and the ++++ guaiac reaction in the stool make one look at the gastrointestinal tract as a source of blood loss, and as a cause of this particular type of blood picture. A malignant growth in the cecum or stomach could produce this type of blood picture. Since the radiologist found no evidence of disease in the examination of the stomach one is likelier to look at the cecum for the primary lesion. I think that the last case I discussed before this group, however, was a case of carcinoma of the stomach with a positive guaiac reaction in which the radiologist considered the examination of the stomach to be negative. The negative x-ray examination certainly does not rule out cancer of the stomach. The pressure defect in the duodenum was said to have been due to the gall bladder. One might

also suggest that this was a peritoneal lymph node, and therefore one should consider the possibility of lymphoma, probably of the abdominal type. The patient had no fever, however, which speaks against Hodgkin's sarcoma or abdominal lymphoma. A lymphosarcoma of the stomach or bowel is a possibility.

I think that the fainting episode three days before admission can be accounted for on the basis of a large gastrointestinal hemorrhage. Since the total blood protein of 7.2 gm per 100 cc following what I think was a hemorrhage seems rather high, one should list plasma-cell myeloma as a possibility. The nonprotein nitrogen of 140 mg per 100 cc merits comment. I think that it can be explained on the basis of cardiac failure, gastrointestinal bleeding and arteriosclerosis. The sudden death could have been due to embolism or a massive gastric hemorrhage.

My first diagnosis, therefore, is rheumatic heart disease, with mitral stenosis, aortic stenosis, arteriosclerosis and cardiac decompensation. I shall list as my second diagnosis cancer in the gastrointestinal tract, probably carcinoma of the cecum.

DR. TRACY B. MALLORY: The level of the nonprotein nitrogen apparently does not bother you, Dr. Rawson.

DR. RAWSON: The patient may have had an old nephritis. The arteriosclerosis probably involved the kidney, however. Also, she quite likely was in shock, which would explain in part the elevated blood nonprotein nitrogen.

DR. WALTER BAUER: Certain findings suggest the possibility of multiple myeloma, but there is nothing that you can "hang your hat on" with certainty.

CLINICAL DIAGNOSES

Uremia
Anemia
Generalized arteriosclerosis
Coronary heart disease
Old rheumatic heart disease, with mitral stenosis
Chronic nephritis
Carcinoma of bowel?

DR. RAWSON'S DIAGNOSES

Rheumatic heart disease, with arteriosclerosis, mitral and aortic stenosis and cardiac decompensation
Carcinoma of cecum

ANATOMICAL DIAGNOSES

Acute rheumatic myocarditis
Calcification of aortic and mitral valves and of annuli of aortic, mitral and tricuspid valves.
Arteriosclerosis, with extreme calcification of aorta and coronary arteries
Chronic glomerulonephritis
Adenocarcinoma of cecum
Colloid adenoma of thyroid gland
Reduplication cyst of duodenum

PATHOLOGICAL DISCUSSION

DR. MALLORY We discovered a wide variety of anatomical findings, most of which Dr. Rawson has predicted correctly. There was a severe grade of heart disease, which was rather peculiar in character. As Dr. Lingley pointed out, in this x-ray film, there was an extreme grade of calcification of the annulus of the mitral valve, and almost equal calcification of the aortic ring. In neither valve was there any interadherence of the cusps or any shortening of the chordae tendineae, so that the gross picture was not characteristic of a chronic rheumatic endocarditis. There even was calcification of the annulus of the tricuspid, which is rare. Considerably to our surprise on microscopic examination the myocardium was full of fresh Aschoff bodies. We can say without doubt that the patient had a terminal acute rheumatic infection, since that is a pathognomonic lesion. There was a carcinoma of the cecum, which was ulcerated. The pressure defect on the duodenum was caused by a cyst, which I believe was congenital in origin, lying between the cecum and the gall bladder. It was lined with an enteric membrane and represented one of those duplications of the intestinal tract often seen in children but rarely in adults. Evidently it had never caused any trouble.

DR. BAUER How large was it?

DR. MALLORY About 4 or 5 cm. in diameter.

There was also an extreme grade of arteriosclerosis in the entire aorta, as seen in the x-ray film. The aorta was calcified from the arch down to the iliac artery. There was likewise marked calcification in the coronary arteries. The thyroid gland showed only an old colloid adenoma. The kidneys were small, weighing 100 gm., and were finely granular and pale—the gross appearance usually associated with chronic glomerulonephritis. On microscopic section an active process was present. There had evidently been extensive destruction of the cortex, and we found an unusually marked sclerosis of the large and intermediate arteries, but little sclerosis of the arterioles, such as one sees in chronic nephrosclerosis. It seems astonishing to me that such a severe renal lesion had occurred without any record of hypertension. You may take your choice in attributing the anemia to the carcinoma or to the nephritis.

DR. RAWSON The patient was in shock.

DR. MALLORY But she had been under competent medical observation for three years and had never shown an elevated blood pressure in that period.

DR. RAWSON Do you think that she had previously had early rheumatic lesions in the heart?

DR. MALLORY I confess that I do not know how to interpret these calcareous lesions of the heart. The majority opinion is that they are rheumatic in origin. There has always been a small minority questioning that assumption, and I have been in

the minority. In many of these cases the most frequent features of rheumatic involvement are missing. For example, in this case, there was no involvement of the valves and no thickening or shortening of the chordae, the two most reliable stigmas of old rheumatic involvement of the mitral valve. But I must grant the terminal rheumatic myocarditis.

CASE 32412

PRESENTATION OF CASE

A forty-five-year-old screen painter entered the hospital because of swelling of the abdomen.

The patient had apparently been well until ten months before entry, when he became aware of increasing fatigue and exertional dyspnea. Five months later he noticed that he "looked thin" in the face and arms, and in another month a black bowel movement occurred. Six weeks before entry the abdomen gradually began to swell, and he caught a "cold," with a persistent hacking cough, occasionally productive of pinkish sputum. He also noticed that the stools were becoming light yellow and that his appetite was diminishing. Nevertheless he continued to work.

Twenty-five years before entry the patient had acquired a chancre on the penis, for which he received antisyphilitic therapy irregularly for the next twenty years. Fourteen years before entry, after a three-month period of treatment, he had become jaundiced but had recovered while still receiving intravenous injections. He admitted drinking two or three glasses of whiskey a day for many years. For two years before entry he had had occasional epistaxes and bleeding gums, with some increase in bleeding tendency during the last two months before admission.

Physical examination revealed a poorly nourished man with a thin face and extremities and a protuberant abdomen. Numerous spider angiomas were scattered over the arms and back. There were dullness and a few medium rales at both lung bases. The heart was normal except for a faint, blowing systolic murmur heard best in the aortic area. The abdomen showed a prominent venous pattern and obvious ascites. The liver edge was felt two or three fingerbreadths below the costal margin. There were scattered hematomas over the legs but no ankle edema. The deep-tendon reflexes were normal.

The temperature, pulse and respirations were normal. The blood pressure was 132 systolic, 95 diastolic.

Examination of the blood showed a red-cell count of 4,400,000, with 75 per cent hemoglobin, and a white-cell count of 4700, with 63 per cent neutrophils and 30 per cent lymphocytes. The total protein was 7.8 gm. per 100 cc., with an albumin-globulin ratio of 0.56. The van den Bergh reaction was 10 mg. direct and 18 mg. total. The pro-

thrombin time was normal. The cholesterol was 327 mg (normal, 150 to 230 mg) and the phosphorus 3.3 mg per 100 cc, the vitamin A 10 units (normal, 40 to 100 units) and the carotenoids 130 units per 100 cc (normal, 100 to 300 units) and the alkaline phosphatase 91 Bodansky units. A cephalin-flocculation test was + in twenty-four hours and ++++ in forty-eight hours. Blood Hinton and Wassermann tests were positive. The urine was normal. A bromsulfalein test (5 mg per kilogram of body weight) showed 36 per cent retention of the dye.

X-ray examination of the chest revealed several linear areas of segmented atelectasis in the left lower lung field and moderate collapse of the right middle lobe. The diaphragm showed adequate excursion, except for somewhat limited motion of the medial portion of the left dome. A gastrointestinal series disclosed extensive varicosities in the lower esophagus.

The patient was placed on a high-calorie, high-protein, high-vitamin, low-fat and low-salt diet, but no clinical improvement was noted. He complained of increased abdominal distention, as well as pain in the right chest posteriorly that was brought on by coughing or by raising the right arm. He also had several epistaxes. Mercupurin and ammonium chloride failed to control the ascites. On the tenth hospital day a paracentesis was performed, and 5500 cc of straw-colored fluid removed. Repeated blood studies on the fifteenth hospital day revealed a total protein of 6.73 gm per 100 cc, with an albumin-globulin ratio of 2.7. The van den Bergh reaction was 1.2 mg direct and 1.4 mg total. The prothrombin time was 25 seconds, with a normal control of 20 seconds. The cholesterol was 208 and the phosphorus 6.8 mg per 100 cc, the vitamin A 50 and the carotenoids 40 units per 100 cc and the alkaline phosphatase 68 Bodansky units. A cephalin-flocculation test was +++ in twenty-four hours and ++++ in forty-eight hours. The bleeding time was one and a half and the clotting time five minutes. On the twentieth hospital day the patient developed edema of the scrotum and prepuce. The radiosodium space was found to be 34 per cent of the body weight, and the thiocyanate space 43 per cent.*

On the twenty-second hospital day the patient began to vomit blood and passed grossly bloody stools. Gastrointestinal bleeding lasted for four days, and numerous blood transfusions were required to keep the patient out of shock. Four days later another 5700 cc of abdominal fluid was removed, following which the patient appeared some-

what improved. A van den Bergh test was 3.2 mg direct and 5.8 mg total. On the thirty-third hospital day an x-ray film of the chest revealed a posterolateral fracture of the eighth rib that had not been seen previously. There were still areas of increased density in both lower lung fields. The ascites appeared to be forming more rapidly with each tap, and ankle edema was becoming noticeable. On the forty-first hospital day the blood phosphorus was 2.6 mg per 100 cc, the alkaline phosphatase 100 Bodansky units and the total protein 6.77 gm per 100 cc, with an albumin-globulin ratio of 0.5. The bromsulfalein test (2 mg per kilogram of body weight) showed 95 per cent retention of the dye after thirty minutes. On the forty-third hospital day the patient again began to vomit blood, and on the following morning the temperature suddenly spiked to 105°F. The patient continued to vomit blood and to pass tarry stools. He went into shock and coma, but the systolic blood pressure returned to 150 after a transfusion. Nevertheless, the patient remained unresponsive, with the eyes half open and wandering from side to side and with the pupils rather large and responding to light. The legs and arms were extended and rigid, but the neck was not stiff. Arm and leg reflexes were hyperactive, and there was a positive Babinski sign on the right. The patient's condition remained unchanged, except that the arms gradually became flaccid. On the morning of the forty-fifth hospital day respirations became gasping and ceased.

DIFFERENTIAL DIAGNOSIS

DR J WALLACE ZELLER. The history is that of a patient with long-standing liver disease who developed rather rapidly progressive hepatic failure and portal obstruction. His death was preceded by bleeding from esophageal varices and possibly also by a terminal event involving the central nervous system.

The summary suggests that the patient had the hepatic facies. Ascites was obvious. A liver two or three fingerbreadths below the costal margin is probably enlarged if the upper level of dullness is in the fifth intercostal space. Apparently the liver was not noted to be definitely nodular. The spleen was not commented on, so that it may be assumed that it was not felt.

The low white-cell count and the alterations in the serum protein are frequently found in severe liver disease. No comment concerning jaundice is made, although the van den Bergh reaction rose to a total of 5.8 mg. At that level clinical jaundice is usually evident. The epistaxes and hematomas of the lower legs are probably related to the prolonged prothrombin time and the alteration in vitamin K metabolism associated with severe liver disease. The results of the bromsulfalein tests reveal marked hepatic insufficiency. The elevation in serum cholesterol, the low serum vitamin A level,

*These measurements were carried out in the surgical research laboratories where normal values for extracellular fluid volume average around 20 per cent of the body weight. Values over 33 per cent of the body weight are usually correlated with gross disturbances of electrolyte metabolism in which ions normally extracellular in position appear to move within the intracellular space. Values between 20 and 33 per cent of the body weight are associated with various grades of clinical edema. (Moore F. D. Determination of total body water and solids with isotopes. *Science* 104: 157-160, 1946.)

elevated alkaline phosphatase and the abnormal phalin-flocculation tests are all changes that might be expected in diffuse liver disease.

The record gives no history of definite injury, which may have been a cause for the fracture of the eighth rib. The fracture was present on the right side and may well have caused the pain in the right anterior chest that was brought on by coughing and raising the right arm. This lesion of course may have been a cough fracture, since we are informed that a persistent hacking cough was present for six weeks before entry. This was most probably due to bronchitis. The areas of atelectasis and collapse that developed may have been due to collections of mucus in the bronchi and small bronchial radicles.

The combination of hepatic failure and portal obstruction naturally brings cirrhosis of the liver to the fore as the likeliest diagnostic possibility. In explaining the etiology of such a lesion we are given at least three possibilities by the history. These are in the order of likelihood: alcohol, syphilis and arsenical antisyphilitic therapy. I believe that we may assume that the intravenous injections the patient was receiving when he became jaundiced were arsphenamine or nearsphenamine. The fact that the jaundice disappeared while the injections were continued makes it unlikely that he had a true arsenical hepatitis. It should be stated that the continuance of arsenical therapy in the presence of jaundice is fearless but unjustified treatment for syphilis. There is a good possibility of producing acute yellow atrophy by such means. The cirrhosis that develops following injury to the liver from arsenic is not true portal cirrhosis. Syphilis itself can cause cirrhosis of the portal type. This patient's syphilitic infection was irregularly, and therefore inadequately, treated. The history and findings are consistent in every way with a diagnosis of alcoholic cirrhosis of the liver. The possibility that alcohol and one or more of the other two factors were simultaneously involved must be considered.

An additional etiologic factor that sometimes causes jaundice in patients receiving arsenical antisyphilitic treatment is epidemic infectious hepatitis. Cases in which this has been traced in clinics to improperly cleaned needles and syringes have been reported. In this regard it is of interest to note that studies of liver biopsies of patients with epidemic infectious hepatitis, arsenical hepatitis and homologous serum jaundice reveal no definite histologic differences in the three conditions.

The gastrointestinal bleeding, which was a prominent feature of the terminal course, undoubtedly had its origin in the esophageal varices. The increased van den Bergh reaction noted at that time may have been partially due to the absorption of blood pigment from the intestine.

During the last day of life the patient was in coma. Various transient paralyses may occur in so-called "hepatic coma." The changes described could have

been due to a left-sided cerebral hemorrhage, possibly associated with the rupture of a syphilitic aneurysm. The extension and rigidity of the extremities could be interpreted as a manifestation of cerebral irritation preceding the stage of paralysis and flaccidity. It is entirely possible that these terminal manifestations could occur without bleeding into the brain, however.

There is good evidence from the history and serologic reactions that this patient had syphilis. Aside from a possible syphilitic factor as a contributing cause of the liver disease and the less likely presence of a syphilitic cerebral aneurysm, there is little evidence from this record of syphilis of other organs. That does not mean, of course, that it will not be found.

My final diagnosis is portal cirrhosis of the liver, with bleeding esophageal varices, ascites and final hepatic failure. It is entirely possible that some fresh destructive lesions of the liver cells will be found, in addition to the old cirrhosis. Alcohol and possibly syphilis are the likeliest etiologic factors to be associated with the cirrhosis. Arsphenamine or infectious hepatitis may have played a contributing role, although they are not usually considered causes of typical portal cirrhosis.

CLINICAL DIAGNOSES

Cirrhosis of liver, ? type
Cerebral hemorrhage or thrombosis

DR ZELLER'S DIAGNOSES

Portal cirrhosis of liver
Bleeding esophageal varices
Ascites
Hepatic failure

ANATOMICAL DIAGNOSES

Hepatoma, with portal vein invasion and thrombosis
Cirrhosis of liver, alcoholic type
Esophageal varices, with massive hemorrhage
Ascites
Necrotizing bronchopneumonia
Fibrous pleuritis
Arteriosclerosis, generalized and coronary
Healing fractures, right seventh and eighth ribs

PATHOLOGICAL DISCUSSION

DR TRACY B MALLORY: This patient showed, as Dr Zeller predicted, a severe cirrhosis of the liver, with esophageal varices from which the numerous attacks of bleeding had come. There was, however, something more. The liver was significantly enlarged, weighing over 2200 gm, and the surface showed a combination of coarse nodularity and fine granulation. On section it was obvious that a large part of the liver had been replaced by tumor, which was spreading in the form of thrombi throughout the intrahepatic portal vein. The thrombus ex-

tended back about 1 cm in the portal vein beyond its point of exit from the liver substance. The identifiable hepatic veins were free from tumor. It is somewhat more usual to find invasion of the hepatic rather than the portal vein. The process was so extensive in this case that the portal obstruction must have been complete. On microscopic examination the tumor proved to be a characteristic hepatoma, with an excellent grade of differentiation, leaving no room for doubt regarding the diagnosis. In the portion of the liver not invaded by tumor a finely granular cirrhosis was present. There were many foci of fresh infarct-like necrosis, presumably due to the venous obstruction. Too little of the cirrhotic portion was uninvolved to permit a definite opinion concerning the type of cirrhosis, it was quite compatible with an alcoholic type. Dr. Zeller avoided the trap of assuming that the rib fracture, without a clear history of trauma, was a pathologic fracture due to metastases. Section through the area of fracture showed active bone callus but no evidence of tumor.

Despite the profound central-nervous-system symptoms the brain showed relatively little. There were no gross areas of hemorrhage or softening, and the arterial system showed no point of occlusion. There was a slight granularity of the ependyma, and a few perivascular foci of lymphocytes could be found. These are compatible with a low grade of central-nervous-system syphilis, and it is doubtful if they were connected in any way with the hepatic insufficiency. Experience with the fulminating type of hepatitis during the war made many of us familiar with the marked central-nervous-system symptoms that may accompany hepatic insufficiency. I saw a few patients with hepatitis who died so rapidly that jaundice never developed. In these patients the central-nervous-system symptoms completely dominated the clinical picture. The anatomic findings in the brain were always disappointing. Slight clouding of the meninges and occasional foci of perivascular cuffing were all that was ever seen. The situation is analogous to that in uremia, in which, again, prominent central-nervous-system symptoms are present but minimal nonspecific lesions can be found only in the brain.

WORLD HUNGER

DESPITE the inevitable association between war and famine, when the ploughshare is beaten into a sword and the farmer must leave his field to wield the sword, the present world famine goes deeper even than the recent world war. Ploughed fields, it is true, have been trampled into mud by the hurrying feet of the world's greatest armies and torn asunder by the destructiveness of their machines, but Nature has also set the stage for her own act in this common disaster.

Over two years ago, in the summer of the Southern Hemisphere, according to a recent issue of *Future*, Latin America was visited with its worst drought in eighty-six years. Argentina's wheat production fell to 60 per cent of normal, and her corn crop to a

third, while Cuba's sugar crop practically dried up at the source. At the same time a drought affected North Africa, breadbasket of France and the Mediterranean basin, so that by the end of 1945 the grain output of this region had dropped from four million to scarcely one million tons. Half the wheat crop and most of the potatoes and beans were failing in South Africa, and this section had to import food by the end of 1945, Australia went dry, and the worst drought in modern times, following heavy rains, destroyed the 1945 crops of the Danube basin. This drought also visited Italy, Spain, France and the Low Countries. Finally the rains have failed in India, Ceylon and Burma, the last-named country being the world's largest exporter of rice. In addition, rinderpest has struck Burma's work cattle, killing a large proportion of them. This year Burma will have no rice to export.

Apparently only the United States, Canada, part of the Middle East and perhaps imponderable Russia are continuing to raise bumper crops, and they must tide over the rest of the world until it can again begin to feed itself. Mass starvation, it is said, has been averted for the time being, but mass malnutrition is dangerously close to the line, and this will prevail at least until the 1947 crops are harvested.

The Department of Agriculture announced in June the failure of this country to meet its export goal of grain and fats and oils for the first quarter of the year, the report of the Secretary of Agriculture to the President on July 8 announced that the fiscal year's grain commitment of 400 million bushels had been met by June 30. This shipment, moreover, was nearly double the requirement for the year that was presented to the Combined Food Board a year ago. Figures, particularly astronomical figures, have little meaning for the individual, impressive as they may appear. Thus, it means little to learn that we have exported, during the fiscal year, 16,700,000 long tons of food unless we know what relation this bears to our normal exports, to our total production, to the exports of other food-producing countries and, particularly, to the world's present needs.

We are passing through an unprecedented period of famine. Are we doing our share in its control, and how successful can we expect its control to be?

COMBINED SULFONAMIDE AND PENICILLIN THERAPY

THE desirability of using both sulfonamides and penicillin in the treatment of infections that are susceptible to both agents is a practical everyday problem. It is amenable, in part, to study in the test tube and in experimental infections of animals, but the final answer must come from a careful analysis of many factors and particularly from the results of clinical experience.

Most but not all of the experimental evidence suggests that the combined use of both agents is preferable to the use of either one alone. Ungar¹ reported that sulfapyridine has a synergistic effect on the action of penicillin against *Staphylococcus aureus* and *Streptococcus haemolyticus* in vitro and in mice. Bigger^{2, 3} found that sulfathiazole increases the dilution in which the inhibitory action of penicillin takes place. He therefore advocated the combined use of the two agents in staphylococcal infections and suggested that the combination might even prove effective against the typhoid bacillus. Kirby⁴ also demonstrated that urea-penicillin and sulfonamide-penicillin mixtures produce greater bacteriostasis of cultures of staphylococci than does penicillin alone. This, however, he found to be purely an additive effect and not a potentiation, since the combination was not inhibitory in concentrations that did not inhibit separately.

The differences in the mode of action of the sulfonamides and of penicillin should be borne in mind. Hobby and Dawson⁵ found that penicillin is most effective during the active multiplication of bacteria and that the concentration of the organisms, within fairly wide limits, is not important so long as multiplication occurs and a sufficient concentration of penicillin is present. The sulfonamides, on the other hand, they⁶ found to be effective only after a lag period during which the organisms multiply while in contact with the drug. Sulfonamides added after organisms had passed the growth acceleration phase produced no bacteriostasis. In addition, the sulfonamides did not act on large numbers of organisms even if they were actively multiplying. They concluded that there was no evidence of any synergistic action of sulfonamides on penicillin.

They also thought that para-aminobenzoic acid⁷ did not increase the effective titer of penicillin but did increase its rate of action, presumably under conditions in which it enhances growth.

More detailed studies by Hobby and Dawson⁵ showed that the results obtained with the combined use of penicillin and sulfadiazine are dependent on many factors. Among these are the concentration of each bacteriostatic agent, the number of organisms present, the environmental conditions allowing growth of the organisms, the susceptibility of the organism to the two agents and the organisms involved.

When penicillin was present in amounts so small as to produce little or no bacteriostasis, sulfadiazine increased the bacteriostatic action provided that the organism was sensitive to the sulfonamide and was present in small numbers. In the presence of an amount of penicillin that by itself was sufficient to produce a definite bacteriostatic or bactericidal effect during the first few hours of incubation but insufficient to yield complete sterilization, sulfadiazine increased bacteriostasis, but again, this occurred only when the number of organisms at the end of the sulfadiazine lag was low. Hobby and Dawson thought that the sensitivity of the organism to sulfadiazine enhanced this effect, but that the degree of sensitivity did not necessarily have to be sufficient to be demonstrable by the usual methods.

With larger amounts of penicillin, its bactericidal action was rapid during the first few hours of incubation and complete sterilization often resulted within five to seven hours. If sterilization was not complete at the end of that time, the presence of sulfadiazine sometimes actually prolonged the lag period or even slightly decreased the bactericidal rate. It appears, therefore, that since the action of penicillin occurs predominantly at the time of cell division, a decrease in the rate of multiplication due to sulfadiazine can decrease the rate at which penicillin acts.

The results of similar studies were briefly reported by Vigouroux and Leyton.⁸ They found that the antibiotic action of penicillin for a number of strains of pathogenic bacteria was reinforced over a wide range by the addition of small amounts of either sulfathiazole, sulfapyridine, sulfadiazine or para-

benzoic acid The incorporation of one of the sulfonamides and para-aminobenzoic acid in the solution with penicillin nullified the potentiation. A penicillin-para-aminobenzoic acid mixture had a more pronounced action on penicillin-sensitive strains, however, than did a combination of penicillin and one of the sulfonamides. The sensitivity of the organism to penicillin played no part in the latter potentiation but, according to these authors, was related to the intrinsic antibacterial action of the substance under investigation. Occasional organisms were encountered that were susceptible to penicillin-sulfonamide mixtures but resistant to each agent applied separately. On the basis of their results, these authors thought that the combination of sulfonamides and penicillin is indicated in certain infections.

There are clinical conditions in which sulfonamides have been found empirically to add to the effect of penicillin. This is particularly true in cases of meningitis due to organisms that are susceptible to both. In such cases the mortality obtained with the combined use of sulfonamides and penicillin, the latter given both intrathecally and intramuscularly, is lower than that obtained with either antibacterial agent used alone. Probably similar results may be expected in other bacterial infections in which there is a tendency of the infection to focalize in inaccessible areas. In such conditions the problems of penetration and diffusion into the infected foci may be an important factor. Differences in the susceptibility of the organisms and the possible additive effect of the two agents, however, may also be significant.

Evidence suggesting that penicillin diffuses into fibrin clots whereas sulfonamides do not⁹ may help to explain the better results obtained with the former in cases of bacterial endocarditis and possibly also in some cases of empyema. The failure of penicillin to penetrate in adequate amounts into the cerebrospinal fluid after systemic administration and probably also the greater susceptibility of the bacterial strains to sulfonamides may account for the better results obtained with sulfadiazine in cases of meningococcal meningitis. Combined therapy has not usually proved advantageous in these circumstances.

In the last analysis, the question of the clinical use of combined penicillin and sulfonamides must be considered as a problem to be decided according to the particular circumstances of any given case. Among other factors one must take into account the desirability of giving frequent injections of penicillin or of subjecting the patient to the possible toxic effects of the sulfonamides. A large increase in the dosage of penicillin is usually more effective than the additional use of sulfonamides. Combined therapy is usually reserved for the severest cases and seems to produce the best results in such cases. This has recently been shown to be true in pneumonia¹⁰ as well as in meningitis.

DEATHS

CLUTE — Howard M. Clute, M.D., of Boston, died September 19. He was in his fifty-seventh year. Dr. Clute received his degree from Dartmouth Medical School in 1914. He was professor of surgery at Boston University School of Medicine and was a member of the New England Surgical Society, the American Surgical Association and the Southern Surgical Association and a fellow of the American College of Surgeons and the American Medical Association. His widow, a son and a daughter survive.

MARSDEN — George Marsden, M.D., of New Bedford, died May 20. He was in his sixty-ninth year. Dr. Marsden received his degree from Johns Hopkins University School of Medicine in 1906. He was a fellow of the American Medical Association.

O'BRIEN — Thomas F. O'Brien, M.D., of Worcester, died September 16. He was in his fifty-first year. Dr. O'Brien received his degree from Harvard Medical School in 1921. He was a member of the New England Obstetrical and Gynecological Society and a fellow of the American College of Surgeons and the American Medical Association.

TINKHAM — Oliver G. Tinkham, M.D., of Newton, died September 10. He was in his sixty-seventh year. Dr. Tinkham received his degree from Tufts College Medical School in 1905. He was a member of the New England Obstetrical and Gynecological Society and a fellow of the American College of Surgeons and the American Medical Association. His widow and a son survive.

BOOK REVIEWS

Hayfever Plants. Their appearance, distribution and time of flowering, and their role in hayfever, with special reference to North America. By Roger P. Wodehouse, Ph.D., cloth, 245 pp., with 73 illustrations. A publication of the Chronica Botanica Company, Waltham, Massachusetts. New York City: G. E. Stechert and Company, 1945. \$4.75.

This valuable monograph brings together for the first time in one volume all the plants whose pollens cause, or are suspected of causing, hay fever. The arrangement is botanical, following the sequence of Engler and Prantl. The plants described fall into two classes — the gymnosperms, which are relatively few, and the angiosperms, which comprise the majority. Botanical and common names are used in the descriptions, which are well written and sufficient for that purpose, including the physical characteristics, distribution, time of flowering and the part the plants play in the causation of hay fever. The numerous illustrations of flowers and pollens should prove useful for identification.

The work is divided into two main parts: the first discusses pollen and pollination and the role of pollen in hay fever, and the second consists of a series of regional surveys.

overing areas in the United States, Canada and Mexico the United States is divided into ten regions, and only the noxious plants are described for each region

An interesting short chapter on the botany of hay fever, in which atmospheric pollen is considered, is found at the beginning of the book, and a selected bibliography is appended to the text.

The book is well printed with a good type on nonglare paper, with good margins

This monograph is recommended for all physicians coming into contact with allergic disturbances, as well as for all medical, public and reference libraries

Facial Prostheses By Arthur H Bulbulian, M S, D D S, 8°, cloth, 241 pp, with 202 illustrations Philadelphia W B Saunders Company, 1945 \$5 60

The reconstructive surgeon is constantly confronted with problems involving prosthetic restorations. The general surgeon in the treatment of cancer and major trauma also not infrequently has cases in which prosthetic restorations, either temporary or permanent, have much to offer. As the author plainly states, the repair of facial deformities is primarily a surgical problem, but there are numerous conditions and circumstances that make surgery impossible or inadvisable. In such a case a prosthetic device may be the answer. Prosthetic restorations of the missing parts of the extremities have long been an accepted orthopedic procedure, but surgery knows little about the possibility of prosthetic restoration of deformities of the face and jaws. One reason is that this specialty has been developed by dentists, and dental literature and subject matter are almost exclusively in dental periodicals and books. Secondly, since this is a highly specialized subject, few in the dental profession have taken the necessary training for the construction of such complicated prosthetic devices as are needed for facial and maxillary problems.

This concise book will undoubtedly fill a great demand, since at the present time there seems to be more interest in facial prosthesis than ever before. The author limits his subject, however, to the diagnosis of artificial restorations of the face, especially of the ears, nose and orbits, he does not consider maxillary restorations, which are often part of such deformities.

According to the opinion of the reviewer, the author has somewhat overemphasized the use of latex as a suitable material for restoration and has not given sufficient emphasis to other materials, such as acrylics.

The book is divided into fourteen chapters, and the classification of subjects is excellent. There are numerous diagrams and illustrations to help the reader in carrying out the technique of restoration. It is a good, small book to introduce prosthetic concepts and technique to the person interested in restorative problems of the face.

Pulmonary Tuberculosis in the Adult Its fundamental aspects By Max Pinner, M D 8°, cloth, 579 pp, with 59 illustrations and 57 graphs Springfield, Illinois Charles C Thomas, 1945 \$7 50

This book, written by a lifelong student of tuberculosis, is a treatise on clinical tuberculosis from the standpoint of the pathologist. In a protean disease like tuberculosis, with its multiple manifestations, a proper understanding of the pathophysiology and its relation to immunity and allergy is of great practical importance. In the preface — the "apologia," as the author calls it — it is stated that the main purpose of the book is not to add another text on tuberculosis or to tell the practitioner how to do this or that, but to harmonize the clinical point of view with the broad aspects of pathological, bacteriologic and immunologic facts.

Out of nineteen chapters, only four can be classed as dealing with bedside observations and treatments. The other fifteen delve deeply into such subjects as histogenesis, immunologic and phthisiogenetic principles, typical lesions of pulmonary tuberculosis, with autopsic examples, and physiologic principles of respiration, to mention only a few of the topics. These chapters reflect the viewpoint of the author, who insisted for many years that an understanding of the basic principles of pathology is the key to intelligent treatment of tuberculosis — this is not to say that he completely neglects the clinical side. Diagnostic criteria are thoroughly discussed,

and medical as well as collapse therapy is fully evaluated. The physiology of respiration and the physiologic and pathological correlations of collapse therapy receive due attention.

An added feature is the abstracted bibliography in which the articles are briefly discussed and comments and criticisms added. This should be most helpful to the reader who can at a glance obtain all the divergent points of view written in the last two or three decades.

The text is written in an easy and clear style and is illustrated by well chosen and excellently reproduced microscopic as well as radiologic pictures. It is a book for the student or the specialist of tuberculosis. It is not intended for the undergraduate or general practitioner. This volume should find a place in the library of anyone interested in any of the many phases of pulmonary tuberculosis.

The Principal Nervous Pathways Neurological charts and schemes with explanatory notes By Andrew T Rasmussen, Ph D Third edition 4°, cloth, 73 pp New York The Macmillan Company, 1945

This outstanding contribution to neuroanatomy, first published in 1932, has been revised at proper intervals. It is one of the best books on the subject and can be fully recommended. The author's position in the field is outstanding, and the book reflects his continued activity in presenting the most recent advances in neuroanatomy. In the new edition he has made definite modifications in some of the charts and minor alterations in others. When doubt exists, the author does not hesitate to query the finding, thus indicating the broad basis of his researches and always seeking a definitive point of view. The book is highly recommended.

Report of the National Health Survey Conducted by Canadian Medical Procurement and Assignment Board 8°, paper, 336 pp Ottawa Edmond Cloutier, 1945

The primary function of the Canadian Medical Procurement and Assignment Board, established in July, 1932, was to obtain physicians for the armed forces and at the same time to provide adequate medical service for the civilian population. It became apparent that the health services of the country needed to be studied, and that this involved physicians, dentists, nurses, hospitals, medical schools, public health, medical research, industrial medicine, and the communities generally. This volume is a report of that study. Although much of the report pertains to the war period, parts of it will be of use in later years. It is doubtful whether this book will be of much interest to the average practitioner of medicine, but it will be valuable to the small group interested in such problems.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

A Bibliography of Infantile Paralysis, 1789-1944 With selected abstracts and annotations Prepared under direction of the National Foundation for Infantile Paralysis, Inc. Edited by Morris Fishbein, M D, editor, *Journal of the American Medical Association*. Compiled by Ludvig Hektoen, M D, and Ella M Salmonsens 4°, cloth, 672 pp Philadelphia J B Lippincott Company, 1946

This selective bibliography covers the clinical and investigative work on infantile paralysis appearing in monographs, pamphlets and theses since its description by Underwood in 1789. Little or no attention is paid to textbooks, systems of medicine, encyclopedias, the official publications of boards of health and pamphlets devoted to general health education, except when representing innovations. The scientific medical literature of the last few years from foreign countries is not complete, since the material has not been easily accessible. Future supplements are planned for the purpose of remedying this defect. The material is arranged chronologically, each reference is numbered, and there are two comprehensive indexes of authors and subjects. The volume is recommended as a reference text for all medical and public-health libraries.

A Primer of Electrocardiography By George Burch, M.D., associate professor of medicine, Tulane University School of Medicine, senior visiting physician, Charity Hospital, consultant in cardiovascular diseases, Ochsner Clinic, and visiting physician, Touro Infirmary, New Orleans, and Travis Winsor, M.D., instructor in medicine, Tulane University School of Medicine, and assistant visiting physician, Charity Hospital, New Orleans 8°, cloth, 215 pp., with 235 illustrations Philadelphia Lea and Febiger, 1945 \$3 50

This primer was written to enable the student who is unfamiliar with the subject to grasp a fundamental knowledge of electrocardiography in the most direct manner. Photographs of electrocardiograms have been excluded but diagrams are literally employed to illustrate typical electrocardiographic patterns. The material is presented from a mechanistic point of view as only with the knowledge of the mechanism is it possible for the reader of electrocardiograms to unravel individual tracings. The presentation has been kept simple and brief as the work is designed to supplement the many monographs on electrocardiography that are now available

The Art of Medicine in Relation to the Progress of Thought. A lecture in the history of science course in the University of Cambridge February 10, 1945 By A. E. Clark-Kennedy, M.D., F.R.C.P., physician to the London Hospital and dean of the Medical School and fellow of Corpus Christi College, Cambridge 12°, paper, 48 pp. Cambridge, England University Press, 1945 75 cents

In this lecture Dr. Clark-Kennedy devotes most of his text to modern medicine in relation to current thought. To complete his task, however, he has made a brief review of the three periods of the past from Hippocrates to Descartes

Clinical Traumatic Surgery By John J. Moorhead, M.D., D.Sc., medical director, New York City Transit System, and consulting surgeon, Post-Graduate Hospital, United States Public Health Service, All Souls (Morristown), Anne May Memorial (Spring Lake), Caledonian, Harlem, Mary Immaculate (Jamaica), Mother Cabrini, New Rochelle, Nyack, Rockland State, St. Francis (Port Jervis) and Yonkers General hospitals 8°, cloth, 747 pp., with 500 illustrations Philadelphia W. B. Saunders Company, 1945 \$10 00

This book has been written with the main idea of placing in one volume all the information necessary to diagnose the usual and most of the unusual effects of accident and injury. The author has summed up his two-score years of active experience in the field and has drawn on the subject matter of his teaching courses at postgraduate medical schools. The work is well printed on good paper but is rather heavy for its size

Government in Public Health By Harry S. Mustard, M.D., LL.D., DeLamar Professor of Public Health Practice, and director, School of Public Health, Faculty of Medicine, Columbia University 8°, cloth, 219 pp., with 11 tables New York The Commonwealth Fund, 1945 \$1 50

Dr. Mustard in this monograph brings out the rapid extension of the field of public health as one of the important trends in modern medicine. He traces the development of state health departments and describes their proper sphere of action. The volume is issued as one of the series published under the auspices of the Committee on Medicine and the Changing Order of the New York Academy of Medicine

One Hundred Years of Gynaecology, 1800-1900. A comprehensive review of the specialty during its greatest century, with summaries and case reports of all diseases pertaining to women. By James V. Ricci, M.D., clinical professor of gynecology and obstetrics, New York Medical College, director of gynecology of the City Hospital, New York, director of gynecology and obstetrics, Columbus Hospital, attending gynecologist and obstetrician, Flower and Fifth Avenue hospitals, New York, and consultant in gynecology and obstetrics, Downtown Hospital, New York 4°, cloth, 651 pp. Philadelphia The Blakiston Company, 1945 \$8 50

The author has attempted to survey the gynecologic literature of the nineteenth century and in conjunction with his previous volume, *The Genealogy of Gynaecology* (1943), provides a history of the subject from 2000 B.C. to 1900 A.D. This work should prove of value as a reference text and should be in all medical libraries

NOTICES

ANNOUNCEMENTS

Dr. Charles Bushold, having returned from the armed services, is resuming practice at 351 Essex Street, Lawrence.

Dr. Henry M. Gahan announces his return from military service and resumption of practice at 19 Washington Street, Medford

Dr. Louis Nathan, having returned from military service, is resuming practice at 276 Commonwealth Avenue, Boston.

EXHIBITION IN COMMEMORATION OF ETHER CENTENARY

The Boston Medical Library, in conjunction with the Boston Public Library and the Massachusetts Historical Society, will hold an exhibition in commemoration of the Ether Centenary, in the Treasure Room of the Boston Public Library, from October 15 to December 15

The material exhibited will occupy all the cases in the Treasure Room and will cover the period from the beginnings of anesthesia, about 4000 B.C., to 1846. Emphasis will be placed on the work of Dr. William T. G. Morton

AMERICAN ACADEMY OF ALLERGY

The American Academy of Allergy will hold its annual convention at the Hotel Pennsylvania, New York City, from November 25 to 27 inclusive. All physicians interested in allergic problems are cordially invited to attend the sessions as guests of the Academy without payment of registration fee. The program has been arranged to cover a wide variety of conditions in which allergic factors may be important. Papers will be presented dealing with the latest methods of diagnosis and treatment as well as the results of investigation and research. Advance copies of the program may be obtained by writing to Dr. Horace S. Baldwin, chairman on arrangements, 136 East 64th Street, New York City, prior to November 10

AMERICAN ACADEMY OF DERMATOLOGY AND SYPHILOLOGY

The first postwar meeting of the American Academy of Dermatology and Syphilology will be held at the Hotel Statler, Cleveland, Ohio, from December 7 to 12 inclusive, with daily symposiums at the Allerton Hotel and teaching clinics at the Cleveland City Hospital. Dr. Howard M. Cole, of Cleveland, will be in charge of local arrangements

ENTERIC INFECTIONS AND THEIR SEQUELAE*

ROGER A. LEWIS, M.D.†

BOSTON

THE acute dysenteric diseases have been studied in various overseas installations throughout the world, but follow-up studies are scarce. Most of the patients in this group were carefully observed overseas, and in many cases the complete clinical record was available, making the follow-up study particularly significant. The cases referred to below were observed on the gastrointestinal section of a United States Army general hospital during the latter half of 1945. Attention was centered on the problems of diagnosis and treatment, since little importance could be attached to incidence in such a selected group of cases.

Overseas records and routine case histories were supplemented by systematic interviews that could be charted in tabular form. All the patients were allowed home for thirty to sixty days before final checkup, to provide a sufficiently long follow-up period after treatment, and practically all were examined with a sigmoidoscope. The laboratory study included at least six stool examinations, one specimen being obtained from sigmoid washings and one after purgation. Stool cultures were supplemented by rectal cultures. When steatorrhea was suspected a twenty-four-hour stool was collected for further observation.

An over-all picture of the cases studied is presented in Table 1, which lists the diagnoses made overseas and in the United States. Amebiasis was diagnosed in over a fourth of the cases. The number of patients diagnosed as carriers of *Endamoeba histolytica* was larger in the United States than overseas. The incidence of hookworm infestation was identical, with as many new cases as old ones that had been cleared of parasites. More patients were found to have strongyloidiasis in the United States than overseas. No new cases of schistosomiasis were discovered, and in several of the old cases negative stools were observed in the United States, where there was a marked increase in the number of diag-

noses of such sequelae of intestinal disease as colitis, chronic diarrhea and steatorrhea.

Of the 105 men in this group, only 2 had never been overseas, 11 had served in the European Theater of Operations, and 92 had been in the Pacific, including the China and India-Burma theaters. Many of those from the Pacific had served in several areas, and a considerable number had no symptoms until they returned to the United States. Some patients had no symptoms of enteric disease and no pathological findings other than eosinophilia and ova in the stools. Such patients are referred to

TABLE 1 Summary of Enteric Diseases

DISEASE	CASES DIAGNOSED OVERSEAS	CASES DIAGNOSED IN THE UNITED STATES		
		ACTIVE CASES	CARRIERS	TOTAL CASES
Ankylostomiasis	29	0	32	32
Amebic dysentery	37	28	15	43
Amebic hepatitis	3	2	0	2
Amebic liver abscess	3	2	0	2
Schistosomiasis	15	7	1	8
Strongyloidiasis	10	10	5	15
Ascariasis	6	1	4	5
Bacillary dysentery	5	0	1	1
Unclassified dysentery	9	1	0	1
Steatorrhea	1	7	0	7
Chronic diarrhea	0	11	0	11
Ulcerative colitis	2	4	0	4
Rectal granuloma	0	3	0	3
Mucous colitis	0	2	0	2
Rectal stricture	1	1	0	1
Appendiceal cyst	0	1	0	1
Totals	124	80	53	138

below as carriers. In Table 1 the infestations that were diagnosed in the United States are divided into active and carrier cases. With hookworm and ascariasis infestation the number of carriers far exceeded those with symptoms. In amebiasis, strongyloidiasis and schistosomiasis there were more patients with symptoms than there were carriers. Patients with active cases were admitted to the ward for obvious reasons, whereas carriers were found through routine examination or because of stool studies ordered after eosinophilia had been noted.

*From the Department of Medicine, Harvard Medical School and Peter Bent Brigham Hospital.

†Research fellow in medicine, Harvard Medical School; assistant in medicine, Peter Bent Brigham Hospital.

In this group of patients the average duration of illness before arrival in the United States was six months, and the average length of hospital stay in the United States was three months. The latent period from exposure to illness varied from one to twenty-four months. Of the entire group of 105 men only a fourth were discharged from the section as fit for full duty.

CARRIERS OF *Endamoeba Histolytica*

A carrier of *E. histolytica* is by definition a person who harbors the organism without having signs or symptoms of disease that might be associated with this infestation. It is well known that when the stool is solid the amebas are usually encysted and

amebic treatment. The last man developed typical amebic dysentery and was found to have trophozoites. Thus, in the 5 cases, 4 patients were eventually treated.

At first, carriers of *E. histolytica* were treated according to the conventional routine described below, Diiodoquin being used instead of chiniofon because of the high incidence of diarrhea with the latter.¹ Nevertheless, 20 per cent of the carriers developed diarrhea with carbarsone. Subsequently carrier cases were treated with vioform alone.

AMEBIC DYSENTERY

In this group of men a diagnosis of amebic dysentery was made overseas in 30 cases and in the United

TABLE 2 Final Results of Treatment in 5 Carrier Cases of *Endamoeba Histolytica* Diagnosed in the Pacific Theater and Followed in the United States

CASE No.	HISTORY OF DIARRHEA	OTHER DISEASE	FINDINGS OVERSEAS	TREATMENT OVERSEAS	SYMPTOMS IN UNITED STATES	FINDINGS IN UNITED STATES	TREATMENT IN UNITED STATES

*Enemas were administered to 13 per cent of patients overseas and to 25 per cent of patients in the United States.

some other disease, and amebas were found during routine stool examinations. In 1 case the organisms were discovered in a purged stool sent to the laboratory after administration of a vermifuge.

The final results in the 5 carrier cases of *E. histolytica* that were found overseas are summarized in Table 2. These men were not given antiamebic treatment overseas because of the presence of more serious disease. One man, nevertheless, remained symptom free, and amebas were not found in the stools. Another remained asymptomatic but was found to harbor cysts. Another remained asymptomatic but was found to harbor trophozoites. One patient developed diarrhea that subsided after anti-

nine months from exposure until onset of the disease in the 20 cases diagnosed in the United States.

Although most of the patients with amebic dysentery were found to harbor trophozoites, cysts were discovered in a significant number (Table 3). In 3 cases the diagnosis was not established until a purged stool specimen was obtained, and in 2 the first positive specimen was obtained from sigmoid washings. Of the 20 cases in the United States complement-fixation tests were positive in only 7 (Table 4). Six cases were severe, 5 leading to ulceration and 1 being accompanied by hepatitis. In none of the 20 carrier cases diagnosed in the United States was the complement-fixation test positive. Con-

trary to the experience of others,² the test was of no value in picking up cases of intestinal amebiasis

Attacks of amebic dysentery in persons returning from overseas were less severe than those occurring overseas but severer than similar infections acquired in the United States. The overseas attacks were almost invariably accompanied by severe diarrhea and the incidence of ulceration was high (Table 3). The overseas recurrence rate of over 40 per cent

scuss, 2 of appendicitis and 1 of mucous colitis. Of the patients who had amebic dysentery in the United States 1 was found to have granuloma and another developed chronic diarrhea. The disproportion in the number of complications in the two groups may have been due to several factors. In the first place, it was chiefly patients with complicated cases that were returned to the United States. Secondly, the overseas attacks were severer. Finally, thorough

TABLE 4 Cases of Amebic Dysentery with Positive Complement-Fixation Tests

contrasts with that of 5 per cent in the United States and may partly have been due to the fact that with one exception patients overseas were not given retention enemas in the treatment of the first attack (Table 3).

Most of the overseas attacks of amebic dysentery were treated with approximately a week of emetine, carbarsone and chiniofon. In Table 5 the treatment

treatment with retention enemas may have prevented some of the complications of amebic dysentery.

Diarrhea following the administration of chiniofon and carbarsone was mentioned above. Another minor toxic effect—vomiting after the injection of emetine—can be obviated by the use of divided doses. Severer toxic reactions to emetine were noted

TABLE 5 Data in 6 Cases of Amebic Dysentery Diagnosed Overseas with Relapse in the United States

TREATMENT	COMPLICATIONS	COURSES OF EMETINE	COURSES OF ORAL CARBARSONE	COURSES OF ORAL CHINIOFON	COURSES OF ORAL DIODIOQUIN	NO OF CARBARSONE ENEMAS
China and India-Burma	Diarrhea watery and bloody stools and ulceration	4	7	2	5	1
Pacific	Diarrhea watery stools and ulceration	0	1	1	1	0
Pacific	Diarrhea watery and bloody stools and ulceration	1	2	0	2	0
Pacific	Diarrhea	1	1	0	0	0
Pacific	Diarrhea, watery and bloody stools and ulceration	1	1	1	0	0
Pacific	Diarrhea, watery and bloody stools and ulceration	3	3	0	3	2

is summarized for the 6 patients who had amebic dysentery overseas with relapse in the United States. This table emphasizes the fact that although most of the overseas cases were accompanied by ulceration few patients received retention enemas. In the United States 25 per cent of the men were found to have ulceration and practically all received enemas.

Of the patients who had amebic dysentery overseas 57 per cent developed complications, including 4 cases of ulcerative colitis, 3 of granuloma, 3 of chronic diarrhea, 2 of steatorrhea, 2 of amebic ab-

when injections had been continued for more than seven days or resumed without an adequate rest period. These reactions consisted of localized palsies. In 1 case an abscess of the deltoid muscle followed emetine injections. One man developed exfoliative dermatitis and hepatitis following carbarsone and gave a history of a similar reaction following neosarsphenamine.

AMEBIC HEPATITIS AND AMEBIC ABSCESS

In this group of 105 men 10 had a total of twelve attacks of amebic hepatitis or abscess, not including

cases of hepatomegaly during the course of typical amebic dysentery. Eight of the attacks occurred overseas, and 4 in the United States. All the men had been in the Pacific, China or India-Burma Theater. The diagnostic factors in these cases are summarized in Table 6.

Prompt diagnosis and treatment of amebic hepatitis may prevent the development of abscess formation, and even after the abscess has occurred treatment may cause resolution without operation or drainage. Of the 8 overseas attacks, at least 5 went on to abscess formation, 4 being drained surgically and 1 by spontaneous rupture into a bronchus. Of

tion relapsed, 1 with amebic dysentery and 2 with amebic abscess of the liver, whereas the patients given adequate medication did not relapse. Although oral treatment may be deferred until after the course of emetine has been completed, it should not be overlooked when the patient becomes asymptomatic, because the effect of emetine on intestinal amebiasis is only temporary.

AMEBIC APPENDICITIS, GRANULOMA AND RECTAL STRICTURE

The incidence of involvement of the appendix in amebic dysentery has been pointed out.³ In 3

the 4 cases diagnosed in the United States 2 went on to abscess formation but resolution occurred without drainage. The chief factors in the early diagnosis of amebic hepatitis and abscess are tenderness and enlargement of the liver, with varying degrees of fever and leukocytosis usually without jaundice and often without amebas in the stools. In addition to fixation of the diaphragm there may be x-ray evidence of pulmonary infiltration, consequently, several patients were treated for pneumonia before amebiasis was suspected. The complement-fixation test, which is often positive in amebic hepatitis, may persist long after successful treatment. It is hazardous to wait for laboratory confirmation in dealing with amebic abscess or hepatitis, and the therapeutic response to emetine is sufficiently dramatic to aid in establishing the diagnosis.

The necessity of treating amebic abscess and hepatitis with either carbarsone or one of the iodine containing oxyquinolines is shown clearly in Table 6. The 3 patients treated without adequate oral medica-

tion relapsed, 1 with amebic dysentery and 2 with amebic abscess of the liver, whereas the patients given adequate medication did not relapse. Although oral treatment may be deferred until after the course of emetine has been completed, it should not be overlooked when the patient becomes asymptomatic, because the effect of emetine on intestinal amebiasis is only temporary.

In 3 patients who had amebic dysentery overseas, granulomatous lesions were found on proctoscopic examination in the United States. One man had diarrhea for four months before antiamebic treatment was given, the lesions disappeared after a course of Diodoquin retention enemas. Another patient, who had had several recurrences of amebic dysentery, developed similar lesions, which cleared up when the stools became negative. A patient who did not receive antiamebic therapy until late in the

se of the disease developed ulcerative colitis and survival in the United States had only a few granulosus lesions that cleared up without further specific therapy. It is interesting to note that at time of discharge these patients were still subject to recurrent attacks of mild diarrhea brought on by stress or food indiscretion.

Stricture of the rectum occurred in 1 patient who had severe dysentery with amebiasis discovered after an appendectomy had been performed. Despite several courses of emetine and oral carbarsone he developed stricture of the rectum. The complement-

are visible the use of chiniofon or carbarsone retention enemas is also recommended. In amebic abscess and hepatitis the emetine is prolonged for a total of eight days, and carbarsone is omitted. This regime, although it was followed closely overseas, led to a relapse rate of 40 per cent in this selected group of cases. Furthermore, diarrhea medication was frequently noted, especially with chiniofon but also with carbarsone.

Recent studies of blood iodine levels suggest that vioform is the best of the available iodine-containing derivatives of oxyquinoline.⁴ Unfortunately,

TABLE 7 Schedules for the Treatment of Amebiasis

TYPE OF CASE	CONVENTIONAL SCHEDULE			SIMPLIFIED SCHEDULE		
	DRUG USED	DOSE gm	PERIOD days	DRUG USED	DOSE gm	PERIOD days

ation test was positive. The weight fell from 205 to 30 pounds, and the patient died after a colostomy.

ANTIAMEBIC DRUGS

The sulfanilamide derivatives are mentioned because they are frequently prescribed in the treatment of dysentery of unknown origin. Sulfadiazine or sulfaguanidine was given to 15 men in this series who were subsequently found to have amebiasis. Although in some cases the original illness may have been bacillary dysentery that provoked or was followed by amebic dysentery, in others it is likely that the sulfanilamide derivatives caused a temporary improvement in the amebic infection. Most of the patients with undiagnosed dysentery treated with the sulfonamides relapsed with typical amebic dysentery — 1 with amebic hepatitis.

The conventional schedule for the treatment of amebiasis is based on a combination of three different types of drugs — emetine, carbarsone and iodine containing oxyquinoline (Table 7). Carriers and patients with mild enteric symptoms were given 0.75 gm of carbarsone daily for a week, followed by 3.0 gm of chiniofon or 1.8 gm of Diodoquin daily for another week. Patients with acute and chronic cases of amebic dysentery were given the same treatment, with the addition of 0.06 gm of emetine daily for six days. In refractory cases and when ulcers

nately, an erroneous statement in the literature that vioform is irritating when given rectally⁵ has been repeated in textbooks and has deterred physicians from employing retention enemas of vioform or Diodoquin. This report was incorrectly based on a previously reported experiment in which the hydrochloric acid derivative of vioform was used.⁶ Vioform is now available in a powdered form that makes an excellent suspension in tap water and is not irritating even when given to patients with severe amebic or ulcerative colitis. Diodoquin, which is also nonirritating, must be powdered before it can be suspended in water. When vioform is used rectally 200 cc of a 1 per cent suspension is given on alternate nights for five doses.

With a knowledge of the chemical stability and nonirritating properties of vioform a new schedule of treatment has been devised (Table 7). This schedule calls for 1.0 gm of vioform daily for ten days, instead of both carbarsone and chiniofon. Emetine is given in all symptomatic cases, and retention enemas of vioform are given concurrently with the oral course of this drug in all but the mildest cases of amebic infection. This schedule of treatment has been effective in the most resistant cases of amebic dysentery, including those from the India-Burma Theater, and has abolished diarrhea medication (Table 8).

ULCERATIVE COLITIS

Five patients in this series were admitted to the hospital with a diagnosis of ulcerative colitis. Four had served overseas in the Pacific Theater, and 1 had never been outside the United States.

One patient gave a history of both amebic and bacillary dysentery, 3 gave a history of amebic dysentery without any known bacillary dysentery, and the patient who had not been overseas gave a history of undiagnosed dysentery acquired during an epidemic.

Three of the cases that occurred after amebic dysentery were extremely mild, and 1 was severe.

TABLE 8 *Incidence of Diarrhea with Antamebic Drugs Used in the United States*

DRUG	ROUTE	NO OF CASES	NO OF CASES WITH DIARRHEA
Chiniofon	Oral	3	2
Carbarsone	Rectal	4	1
Carbarsone	Oral	32	4
Diodoquin	Rectal	2	0
Diodoquin	Oral	36	0
Vioform	Rectal	4	0
Vioform	Oral	12	0

The other case, although not severe, had relapsed several times.

These men were all given a course of sulfadiazine, and 3 of them were also given a course of vioform. Four patients recovered, and 1 who failed to improve was transferred to another hospital.

CHRONIC DIARRHEA

The term chronic diarrhea is used to describe a condition that does not fit any other clinical syndrome. The condition, which is characterized by recurrent, self-limited attacks of mild diarrhea, is usually brought on by exercise, spiced foods or alcoholic beverages. It does not include ulcerative colitis, mucous colitis or patients with psychiatric disorders. The final diagnosis was chronic diarrhea in 10 cases in this series. Actually the incidence of this condition was greater, but when a diagnosis of amebic dysentery was made in the United States the recurrent diarrhea was considered a residual symptom of amebic infection and a diagnosis of chronic diarrhea was not made. This syndrome was also noted among persons on the hospital staff who had been overseas and had been evacuated to this country under the rotation policy.

Most of the men with chronic diarrhea had served in the Pacific, China or India-Burma Theater. All had a history of intestinal disease, and in 80 per cent a definite diagnosis of amebic dysentery had been made. One of the men suffering from chronic diarrhea had been infected with strongyloides and developed diarrhea when he was given gentian violet. In some cases the diarrhea was aggravated by treatment with carbarsone. About half the men had

hookworm infestation, and some had received several courses of tetrachlorethylene. Other, visible factors in the production of this syndrome included exposure to the hardships and food of overseas installations, especially in the zone. In these cases the diarrhea was often accompanied by cramps and a feeling of malaise that cleared up when the attack subsided. There was usually relatively slight weight loss. Physical examination was not remarkable except for tenderness over the colon or small intestine. Laboratory studies were entirely negative, including x-ray examination of the gastrointestinal tract, twenty-four-hour stool fat analysis, microscopic examination of the stool and repeated rectal cultures.

Most of the patients with chronic diarrhea were not given any specific therapy and showed gradual improvement with rest and diet. Sulfadiazine was tried in a few cases without benefit. Vioform, which caused considerable improvement in the 2 cases in which it was given, deserves further trial when the history is of amebic infection.

STEATORRHEA

Most studies of fat excretion have been based on a chemical partition of the dried stool. It is known that 5 to 10 per cent of ingested fat is excreted, but

TABLE 9 *Approximate Total Fat Excretion in Twenty-Four Hours on a Diet of 100 Gm. or Less of Fat*

ever, so that with a normal intake of 100 gm. of fat the twenty-four-hour stool should not contain more than 10 gm. of fat.⁷ It is also known that diarrhea of any type may cause an increase in fat excretion but that more marked disturbances occur in pancreatic disease and sprue. For the purposes of this study a twenty-four-hour stool specimen was deemed adequate because of the presence of diarrhea. An aliquot of the moist stool was analyzed for total fat by the Fowweather method.⁸

the total fat excretion in twenty-four hours measured in 26 cases (Table 9). Normal persons excreted 1 to 5 gm. Patients with mild diarrhea excreted 3 to 9 gm. There were 9 patients who excreted 12 to 80 gm., including 1 with ulcerative colitis, 1 with pancreatogenous steatorrhea and 7 with a syndrome closely resembling tropical sprue.

Pancreatogenous diarrhea may be differentiated from sprue by several laboratory tests. In sprue the stool is bulky, there may be a lowering of the serum calcium and phosphorus, as well as the hemoglobin, and the glucose-tolerance test tends to be flat. In pancreatic disease the stool contains undigested fat particles and an increased amount of nitrogen, there may be an increase in the serum amylase, and the glucose-tolerance test may be elevated. The only case of pancreatogenous steatorrhea in this series showed all the abnormalities mentioned.

SPRUE

One of the characteristic features of sprue is that it occurs at a variable period after a person has left the tropics.⁹ It seems quite likely that steatorrhea begins long before the development of classic sprue, since it takes some time to deplete the mineral and vitamin stores. This intermediate stage in the development of sprue has been called presprue or incomplete sprue.¹⁰ Of the 7 cases in this study only 3 were diagnosed overseas.

The case histories showed several common characteristics (Table 10). All the men had served in New Guinea or the Philippines. The latter location is a well known source of a spruelike disease that has been considered a complication of amebiasis.¹¹ The period of exposure in the tropics varied from one to three years. All the men gave a history of dysentery, and amebic infection was proved in 2 cases. The average weight loss amounted to 47 pounds.

Associated with the weight loss these patients showed wasting of the musculature, looseness of the skin and marked pallor. Transient soreness and redness of the tongue in 5 of the 7 men went on to ulceration in a few cases. Gaseous distention and abdominal tenderness were frequently noted. Proctoscopic examination showed hyperemia in 4 cases. X-ray studies disclosed redundancy of the colon in 3. One man developed a peripheral neuritis.

The total bulk of the twenty-four-hour stool was markedly increased, with an average weight of 850 gm. The stool was light in color and varied from soft to liquid, with a tendency to adhere to the glass container. The total fat excretion was markedly increased, averaging 36 gm.

Gastric analysis revealed the presence of a variable amount of free acid in all cases. The serum proteins were normal or slightly less than normal. In a few cases the blood calcium and phosphorus were below normal. The average red-cell count was 4,200,000,

and the average hemoglobin 12.5 gm. The glucose-tolerance test showed a marked tendency to be low and flat, the average maximum value after 100 gm of glucose was only 115 mg per 100 cc.

Of the 2 patients in whom a diagnosis of sprue was made overseas only 1 was given a low-fat diet and liver extract. This man showed marked improvement and was convalescent when he arrived in the United States. The other patients were in poor condition, despite the fact that some of them had learned to avoid fatty food.

In the United States the patients were put on a strict low-fat diet. The regular hospital diet contained 100 gm of fat, the high-calorie diet 150 gm, and the strict low-fat diet only 40 gm. In this diet the rest of the calories were furnished by 400 gm of carbohydrate and 120 gm of protein. In addition to the diet, each patient was given 5 cc of crude liver extract twice weekly. On this regime the diarrhea improved, the cramping ceased, and there was a rapid weight gain. It was not possible to follow all these patients, but 4 were well enough to be discharged from the hospital, 2 were sent to convalescent hospitals and 1 was transferred to another general hospital.

Although the eventual prognosis in these cases cannot be determined, it is possible that the development of classic sprue was prevented by early treatment of the underlying metabolic disturbance, that is, steatorrhea.

HOOKWORM INFESTATION

Of the 45 cases of hookworm infestation in this series 13 were diagnosed overseas only, 16 were diagnosed overseas and in the United States, and 28 were diagnosed for the first time in the United States. Almost all the men were exposed in the Pacific Theater. These figures do not give a fair picture of the incidence of infestation, however, because the entire group was specially selected from the enteric disease ward.

None of the men observed in the United States had symptoms that could be ascribed to hookworm infestation. There is no doubt that symptomatic hookworm disease was encountered overseas, but sufficient treatment was given to clear the symptoms before the patients returned to the United States.

In the cases that were diagnosed overseas and were not complicated by other parasites, the average eosinophil count was 16 per cent. When these men arrived in the United States those with negative stool findings had an average eosinophil count of 2 per cent, and those with positive stool findings had an average eosinophil count of 13 per cent. In cases diagnosed in the United States for the first time the average eosinophil count was 9 per cent. The total white-cell count was sometimes increased, the maximum noted in this series being 18,000.

Overseas the treatment for hookworm infestation consisted almost entirely of tetrachlorethylene in doses of 3 cc. In some cases the drug was given in larger doses, and in some, hexylresorcinol was employed.

The results of hookworm treatment are shown in Table 11. About half the men treated overseas were found to have negative stools, and about half were found to have positive stools when they arrived in the United States, regardless of the number of treatments that had been given. Treatment in the United States gave similar results, even when the dose of tetrachlorethylene was increased to 4 cc. and 1 cc. of oil of chenopodium was added.

Although tetrachlorethylene was no more effective in the United States than overseas, few patients received more than two courses of the drug even when

tions that preceded the first positive findings may have been associated with the incubation period. The patient, who was overseas in April and May, returned in June with a white-cell count of 14,000, with 43 per cent eosinophils. Repeated stool examinations were negative until the middle of July, when larvae of strongyloides were found.

Only 5 of the 16 patients with strongyloidiasis were asymptomatic (Table 12). Eleven men complained of cramps, and 5 were also troubled with diarrhea. Tenderness on abdominal palpation was a frequent finding.

It is interesting to note that the patient was cured in only 1 of the 10 cases discovered overseas. This may in part have been due to the fact that enteric coated gentian violet was not generally available outside this country. Of the patients treated in the

TABLE 10 *Data in 6 Cases of Sprue Contracted in the Pacific Theater*

OVERSEAS SERVICE	CHIEF SYMPTOMS OVERSEAS	CHIEF TREATMENT OVERSEAS	TRANSFER DIAGNOSIS OVERSEAS	CONDITION OF TONGUE	PROCTOSCOPIC EXAMINATION	BARIUM-ENEMA EXAMINATION
mo						
16	Diarrhea and vomiting	Antiamoebic and dietary	Dysentery (unclassified)	Atrophic	Negative	Redundant colon
34	Diarrhea and vomiting	Transfusion and vitamins	Malnutrition and anemia	Sore and reddened	Negative	Negative

22	Diarrhea and cramps	Dietary	Sprue	Sore and reddened	Hyperemia of mucosa	Redundant colon

the stools remained positive, and some patients were not held in the hospital long enough to determine whether ova were still being excreted. This indicates that the policy on the gastrointestinal ward was to limit retreatment to one course of tetrachlorethylene. Inasmuch as hookworm infestation is self-limited, this policy was considered safe and in fact beneficial to the patient.

STRONGYLOIDIASIS

Strongyloidiasis was found in 12 men from the Pacific Theater, in 2 from the China and India-Burma theaters and in 2 from the European Theater. Most of the diagnoses were made from routine stool examinations, but some were arrived at only after repeated studies made to find the cause of eosinophilia. In 1 case the long series of negative examina-

United States, however, at least 2 still had positive stool findings at the time of discharge. One of these men had received intravenous and intraduodenal gentian violet, as well as a thirty-day course of the oral preparation.

The situation is further complicated by the fact that strongyloidiasis is a self-perpetuating organism.¹² The need for further observation and study of this disease is obvious.

BACILLARY DYSENTERY

No patients with active cases of bacillary dysentery were admitted to the hospital in the United States during the course of these studies. One carrier of *Shigella* organisms was found who had had bacillary dysentery while in the Pacific Theater.

the other patients in this series had bacillary enteric overseas, but stool and rectal cultures were negative in the United States. One of the men who had had bacillary dysentery, however, developed mucous colitis, and another had had both bacillary and amebic dysentery developed ulcerative colitis. There were no other cases of enteric disease following bacillary dysentery, despite its widespread occurrence overseas.

MISCELLANEOUS PARASITES

Five proved cases of schistosomiasis are included in this series because of concomitant amebiasis. Four of these patients were found to have ova in the stools both overseas and in the United States, whereas stool examinations in 2 cases were positive overseas.

There were several asymptomatic carriers of *Trichuris trichura*, *Giardia lamblia* and *Trichomonas hominis*. No treatment was given to these patients.

SUMMARY

The records of 105 patients studied on the gastrointestinal ward of a general hospital are analyzed. Attention is drawn to the latent and chronic nature of the diarrheal diseases acquired while the patient was serving outside the United States.

Carriers of *Entamoeba histolytica* should be treated to prevent the subsequent development of dysentery. The importance of sigmoidoscopic examination and the collection of purged stools in the diagnosis of amebiasis is emphasized. The need for early clinical diagnosis in amebic hepatitis and for prompt

it negative in the United States. In 4 cases a clinical diagnosis of schistosomiasis had been made overseas, but since ova were not found overseas or in the United States the diagnosis is not certain. It is interesting to note that no carriers or mild cases of schistosomiasis were found in patients admitted to the hospital with a diagnosis other than schistosomiasis. All the patients with schistosomiasis were transferred to a special ward for treatment and follow-up study after the amebiasis had been brought under control. Five of the men in this group were found to have schistosomiasis and were treated overseas; they were stool negative on arrival in the United States. Five other patients treated in the United States for the first time were also cured after one or two courses of methylresorcinol.

treatment with emetine, as well as with further medication with carbarsone or one of the iodine containing oxyquinolines, is stressed. Tissue invasion, usually evidenced by a positive complement-fixation test, may produce stricture of the rectum and appendicitis, as well as granulomatous lesions. Patients with amebic dysentery who show any evidence of rectal involvement — either by proctoscopic examination or from the presence of blood in the stools — should be treated with retention enemas. Contrary to current belief, vioform suspension is nonirritating and most convenient for retention enemas in the treatment of amebic dysentery. It is advisable to give an oral course of this drug in conjunction with retention enemas, thus obviating the use of chiniofon and carbarsone, which are likely to aggravate diarrhea.

Ulcerative colitis apparently develops after severe amebic dysentery as well as after bacillary dysentery. Men who have served overseas, especially those who have had amebic dysentery, are subject to re-

the loss of a great deal of weight there may be signs of vitamin deficiency. These patients, well to a diet strictly limited in fat and high in protein and carbohydrate.

current attacks of diarrhea. This condition responds gradually to rest and diet and is sometimes helped by antiamoebic treatment.

A large proportion of cases considered as unclassified dysentery will be found to have steatorrhea.

Hookworm infestation is frequent in troops in the Pacific area. Symptoms from this infestation are rare, and although treatment with tetrachlorethylene may not eradicate all the parasites it is not necessary to continue treatment after two courses of the drug.

SURGICAL TREATMENT OF ASCITES

ROY C. CROSBY, M.D.,* AND EDWARD A. COONEY, M.D.†

BOSTON

ASCITES is a problem frequently encountered and often unsatisfactorily treated. An adjunct to the therapy of ascites has been tried in a limited number of cases and has seemed sufficiently helpful to warrant reporting.

Attempts to obtain more lasting relief from ascites have been many and varied. In 1896 Drummond and Morison¹ reported the first surgical treatment of ascites. Talma,² in 1898, is usually credited with the original suggestion for the surgical relief of ascites, and the operation — omentopexy — has come to be known as the Talma-Morison operation. Morison's patient lived two years after the operation. Monprofit³ reported 224 cases treated by the Talma-Morison operation up to 1904. Thirty-one per cent of this group were successfully relieved of their ascites for varying periods. Noetzel,⁴ in 1919, and Mayo,⁵ in 1924, reported smaller groups in which the operative mortality was high and good results relatively few. Hughson⁶ considered the operation to be without value. Grinnell⁷ obtained relief from ascites in only 2 of 23 patients operated on. In 1943 Cates⁸ reviewed the patients treated by omentopexy at the Los Angeles County Hospital during the previous five years. Thirty-eight patients who were operated on were compared with 172 treated medically; follow-up study led to the conclusion that the surgical intervention did not improve the prognosis. Operative mortality was high. 42 per cent of the patients died within two weeks of the operation, presumably because of under-nutrition, the susceptibility of patients with cirrhosis of the liver to shock and tympanites, poor wound healing associated with hypoproteinemia, and

the greater danger of administering anesthesia because of failure of the cirrhotic liver to detoxify the anesthetic agent.

The operation itself is a simple one. An epigastric incision is made just to the right of the midline through the abdominal wall, the peritoneal cavity is opened, and a portion of the omentum is withdrawn. A second lower incision is made through the skin and muscle down to the posterior aponeurosis and peritoneum. The rectus muscle is separated from its posterior attachment, and the omentum is drawn from the upper incision down into the extraperitoneal pocket thus formed. The rationale is simply to establish a portal collateral circulation via the omentum and the vessels of the abdominal wall. All the earlier attempts at surgical control of ascites were somewhat impeded by failure to take into consideration and to treat adequately other contributory factors, such as hypoproteinemia and poor liver function. Evaluation of omentopexy over a long period, however, seems to indicate that it leaves much to be desired.

Another attempt at the surgical treatment of ascites is described by Ferguson,⁹ who reports a case in which a right nephrectomy was performed and the renal pelvis anastomosed to the peritoneum along the peritoneal gutter beside the ascending colon. Since omentum blocked the outlet in this position, the site of anastomosis later had to be shifted to the lower part of the right rectus muscle. This, of course, simply provided an outlet for the ascitic fluid via the bladder and thus obviated repeated paracenteses. The protein content of the fluid, however, was still lost to the patient.

A third method, aimed at relieving the portal hypertension of cirrhosis, is described by Blakemore and Lord¹⁰ and by Whipple¹¹. In 5 cases the blood was shunted from the portal to the caval system by removal of the spleen and left kidney and by

anastomosis of the splenic and left renal veins by means of an endothelial-lined vitallium tube. In 5 other cases portacaval shunts (Eck fistulas) were produced by end-to-side anastomoses of the portal vein to the inferior vena cava over vitallium tubes and ligation of the portal vein between operations. Whipple stated that all 10 patients survived the operation but that a follow-up period of three years or more would be required to determine the value of these portacaval shortcircuiting procedures.

The method of treating ascites described below is by the insertion of a glass button into the abdominal wall. The origin of this therapeutic device is obscure. It was first encountered by one of us (RCC) in New Orleans, where it was used by Dr. Julian Rickles,¹² who, in turn, had heard about it from Dr. Douglas Donath,¹³ who had been using it at the Marine Hospital in New Orleans. Communication with Dr. Donath revealed that he, too,

FIGURE 1 Abdominal Buttons

A — the button used by former workers. B — the button with an added glass plate to prevent omental impaction in the core.

had tried to ascertain the origin of the glass button and had traced it as far as a British Army surgeon in Egypt but had been unable to learn the name of its originator. One reference to the use of a similar device was found in the literature. Tannahill,¹⁴ in 1930, reported a single case of cirrhosis of the liver with ascites treated by the insertion of two glass buttons — one under the sheath of the upper rectus muscle and the other lateral to it in the upper quadrant. These were smaller buttons than those used by us, and Tannahill called them "Paterson buttons." He attributed the idea to Professor Peter Paterson, of Glasgow University. His patient required one postoperative paracentesis but subsequently did well.

Lichtman¹⁵ states that in 1922 Boccardo used a glass tube resembling a collar button to drain

ascitic fluid into the subcutaneous tissues. reference was not found in the literature.

The button as used by previous workers is in Fig 1A. We have added the top plate, as in Fig 1B. The button can be made by any petent glass blower. The flanges are approximately 2.0 cm in diameter, and the bore is 0.6 cm. The button itself varies from 1.0 to 1.5 cm in length and the added glass plate lies approximately 0.6 cm below the lower flange.

This button is inserted into the anterior rectus sheath, the lower flange, with the glass plate, lying just inside the peritoneum. The rectus sheath fat between the flanges, and the distance between the flanges can be varied to accommodate various thicknesses of the sheath in different patients. The anterior rectus sheath is sutured tight under the upper flange, and the skin closed. The function of the button is simple: it merely allows ascitic fluid to pass through its core and thus into the subcutaneous tissues, where it is absorbed as edema fluid. We have added the top plate in an attempt to prevent the omentum from blocking the outflow of ascitic fluid by becoming impacted in the core of the spool as happened in some cases in which it was used in New Orleans.¹²

One great advantage of this therapeutic device is its ease of application. It is known that patients with hepatic cirrhosis do not tolerate major surgery well. Malnutrition, susceptibility to shock and tympanites contribute greatly to the high operative mortality. Secondly, wound healing is poor unless vitamin C and a great deal of protein, preferably as intravenous plasma or amino acids, are given. Finally, the anesthetic tolerance is poor, since the damaged liver detoxifies the anesthetic agent poorly, yet large amounts of anesthetic are usually required for satisfactory anesthesia in patients with alcoholic liver cirrhosis. For these reasons major surgical procedures such as those outlined above are at best limited in their applicability.

The insertion of the button is a simple procedure and may be done under local anesthesia if desired, although spinal anesthesia was used in all our cases. The site selected may be over either the right or the left rectus muscle below the level of the umbilicus. A 6 cm midrectus incision is made and deepened through the muscle layer to the peritoneum, which is nicked to allow the insertion of a suction tube to remove the ascitic fluid. The opening in the peritoneum is then made the same length as the skin incision. The peritoneum and anterior rectus fascia at the lower margin of the wound are grasped with an Ochsner clamp, and the fat layer below the lower end of the wound freed up over an area from 8 to 10 cm below the lower margin of the wound. After retraction of the skin and fat layer at the lower part of the wound downward and pulling upward on the Ochsner clamp

holding the peritoneum and anterior rectus fascia, a stab wound is made about $\frac{1}{4}$ cm below the lower margin of the wound going through the anterior rectus fascia, muscle and peritoneum. The stab wound is enlarged enough to allow for the insertion of the button. A silk purse-string stitch is then taken in the peritoneum around the button to fix it in place, a similar stitch is taken in the anterior rectus fascia after the rectus muscle has been placed between the flanges of the button. The main wound is then closed in layers without drainage.

Ideally, of course, sufficiently good treatment of the underlying disease so that ascites disappears spontaneously is the goal of therapy. Unfortunately, such a result is not always or even often possible, diuretics and repeated paracenteses are the rule. The mechanism of the production of ascites in cirrhosis is not entirely clear. It has been suggested that ascites is the result of hypoproteinemia, although the relation between ascites and the serum protein or albumin level is not always a parallel one. It has also been suggested that ascites is the direct result of portal hypertension — a hypothesis difficult to prove or disprove. The theory of Ralli et al.¹⁸ that the ascites is due to an antidiuretic hormone — possibly to failure of the diseased liver to destroy posterior pituitary antidiuretic hormone — is an interesting concept that fails, however, to explain the absence of edema in many patients with definite ascites.

The avoidance of repeated paracenteses is the purpose of the abdominal button, which is a purely symptomatic measure but has another advantage: it returns to the patient his own ascitic fluid together with its protein content. The protein loss from repeated paracenteses is not inconsiderable. In some clinics it is the practice to reinject the ascitic fluid intravenously so that the protein content will not be lost to the patient. The abdominal button does this automatically, the ascitic fluid draining through the core of the button becomes edema fluid as fast as it is formed and is absorbed as such. Thus the button may be regarded as a mechanism by which the patient with ascites is given a constant slow clysis of his own ascitic fluid so long as such fluid is formed.

This procedure was employed in 7 cases. One recent case is not included in this report. The following case report is typical.

CASE 2 W. D. (P. D. H. 14-421), a 48-year-old food broker entered the hospital on April 23, 1945. The alcoholic intake had averaged a quart of Bourbon whiskey daily for many years. During the previous year food intake had been confined to a small evening meal daily. In May, 1942, a Civil Service physical examination had been negative. Except for a bleeding hemorrhoid in October, 1942, the patient remained well until the winter of 1944-1945, when he began to feel weak and tired. He lost 20 pounds in weight during the winter, and 5 weeks before admission he developed an upper respiratory infection, with general malaise followed a week later by jaundice. At that time he completely lost his appetite, the food intake being confined to fruit juices. Alcohol was not used. Self-administered "salts" for several days produced diarrhea and rectal bleeding. Bowel

movements were otherwise light in color, the urine was dark and there was progressive swelling of the abdomen. Four days before admission abdominal paracentesis yielded 6 liters of fluid. Following this there were dysphagia and nausea, and a small amount of blood was vomited.

Examination revealed an obese, deeply jaundiced and rather acutely ill and confused man. The heart and lungs were essentially normal. The abdomen was tense and protuberant, extending well above the costal margin. There were shifting dullness and a fluid wave. The liver was palpated $\frac{1}{4}$ fingerbreadths below the right costal margin. The spleen was not felt. No edema was noted. Spider telangiectases were present.

Examination of the urine showed a + test for albumin, a ++++ test for bile and approximately 1 white cell and 1 red cell per high-power field. Examination of the blood showed a red-cell count of 3,340,000, with a hemoglobin of 64 per cent, and a white-cell count of 20,500, with 90 per cent neutrophils, 31 per cent of which were band cells. The serum bilirubin was 28 mg per 100 cc, 21 per cent of which was direct, the nonprotein nitrogen was 36 mg, the total protein 5.9 gm, the albumin 2.9 gm and the globulin 3.0 gm per 100 cc. The blood Hinton test was negative. The sedimentation rate was 29 mm in 1 hour. The stools gave ++++ benzidine and guaiac reactions. The bromsulfalein test showed 98 and 82 per cent retention of the dye at 30 and 60 minutes respectively. A cephalin-flocculation test was +++ in 24 hours. Two weeks later the total protein was 5.5 gm, the albumin 1.7 gm and the globulin 3.8 gm per 100 cc, and the bromsulfalein test showed 67 and 48 per cent retention of the dye at 30 and 60 minutes respectively. The cephalin-flocculation test was ++ in 24 hours. The serum bilirubin was 24.8 mg per 100 cc indirect and 19.8 mg direct. The prothrombin time was 50 per cent normal throughout.

The patient was given a high-protein, high-carbohydrate, low-fat, low-salt diet, with 576 gm of powdered yeast three times daily and supplementary thiamine chloride and vitamin B complex by injection. Crude liver extract and vitamin K were also given by injection. Ammonium chloride and Mercupurin provided a fair diuresis. Abdominal paracentesis was discontinued after 900 cc of fluid had been removed, but drainage continued for several days, a total of 8 pounds in weight being lost during the hospital stay. The patient was discharged only slightly improved and advised to remain on diet and vitamin therapy.

Following discharge the hepatitis improved slowly but steadily. The color of the stools became normal, the urine became lighter, and the patient felt somewhat improved. Repeated abdominal paracenteses were required, however, to control the ascites, and for this reason on July 13, after the jaundice and hepatitis had almost disappeared, an abdominal button was inserted under spinal anesthesia. The postoperative course was uneventful. On getting up the patient developed marked edema of the thighs, scrotum and penis, despite the fact that all the ascitic fluid had been aspirated at the time of operation. This edema was gradually absorbed, however, but when the patient was last heard from slight edema was noticed (evidence that ascitic fluid was still forming but was draining via the button). Shortly after the operation he reported that he felt better than he had in years. Six months postoperatively he was completely symptom free, except for minimal edema of the lower abdominal wall, had resumed full activities and had regained his normal weight and strength.

A summary of the data and results in all 6 cases is presented in Table 1. As can be seen the 5 cases were fairly typical of Laennec's cirrhosis in various stages of compensation. Four patients had been confirmed alcoholic addicts for many years. The patient in Case 5 denied the use of alcohol, and the dietary history as given was adequate, yet the clinical picture left little doubt of the diagnosis. All patients showed typical spider telangiectases, and all had low serum proteins, with reversal of the albumin-globulin ratio. The prothrombin time was significantly prolonged in all except Case 4, and bromsulfalein retention was marked in all.

†After operation

‡This patient had chronic constrictive pericarditis

except Case 3, in which the test was not done because of the obviously severe hepatic insufficiency

The results may be considered good in all cases except Case 3, in which the operation was performed, despite a severe hepatic insufficiency, because of constant rapid accumulation of ascitic fluid. This patient was confused and deeply jaundiced, and showed the fetor hepaticus of cholemia throughout the hospital course. Autopsy revealed peritonitis and a stomach and upper bowel full of blood from a ruptured esophageal varix, in addition to advanced cirrhosis. A fatal outcome could have been predicted even without the button insertion and the peritonitis, which was obviously directly attributable to the button.

Other therapy that these patients received, of course, cannot be disregarded. This consisted of a high-protein, high-carbohydrate, low-fat diet, as well as 50 gm of brewer's yeast daily, 3 gm of choline chloride a day and, in most cases, vitamins A, B and D. Diuretics were given and preoperative abdominal paracenteses were performed as needed. The patient in Case 1 also received large amounts of plasma before operation.

Because it might be argued that these patients were cured of ascites by nonspecific measures — in other words, by the intensive medical therapy directed toward the underlying disease — Case 6 is of particular interest. This patient had chronic constrictive pericarditis. She was first admitted to the Joseph H Pratt Diagnostic Hospital in 1940, when the diagnosis was established. Pericardiectomy was contraindicated because of severe underlying myocardial damage. Ascitic fluid, which had continuously accumulated for over six years, required repeated paracenteses, despite fluid and sodium restriction as well as the use of diuretics. The therapeutic regimen was altered only in that a button was inserted, despite the fact that a mechanically impaired heart and a high venous pressure rendered mobilization of the consequent edema difficult if not impossible. Since paracenteses were becoming necessary in increasing frequency and the potential absorptive surface is greater for edema than for ascites a trial of the button seemed warranted in this case. On a continued regimen of restricted salt and fluid the patient remained relatively free of symptoms after the insertion of the button. The edema of the lower abdominal wall and thighs continued to be troublesome. As anticipated the edema fluid was mobilized with difficulty, and mercurial diuretics were therefore frequently required. The patient was able to carry on restricted activities, however, and felt well. Adequate function of the button may be assumed from the absence of ascites, as well as the constant accumulation of edema.

It is too early to arrive at any final evaluation of the results. Bearing in mind that the only purpose of the abdominal button is the relief of ascites, it may be said that in this respect it is successful.

Adequate function of the button was assured in Cases 2, 4, 5 and 6 by continuous slight edema of the lower abdominal wall and thighs, as well as by the absence of ascites. It is possible that in Case 1 ascitic fluid simply stopped forming as a result of medical therapy. Other users of a button have occasionally found that the omentum became impacted in the core and thus prevented adequate functioning of the button. This complication did not occur in any of the present series, possibly owing to the addition of the top plate. The one patient (Case 1) who was readmitted for follow-up studies showed clinical recovery. Patek's¹⁷ criteria for clinical recovery are weight gain and strength for full activity, disappearance of ascites, edema and jaundice, and return to normal of laboratory findings. Preliminary reports indicate that all the cases of cirrhosis, except Case 3, fulfill such criteria. The patient in Case 6, of course, benefited only in that the ascites was converted to edema, which is perhaps more easily dealt with.

SUMMARY

The literature concerning previous attempts at surgical treatment of ascites is reviewed. A method for the treatment of ascites is presented. This consists of a glass button inserted into the lower rectus sheath so that ascitic fluid may drain from the peritoneal cavity into the subcutaneous tissues and be absorbed as edema fluid.

Five cases of Laennec's cirrhosis of the liver and 1 of chronic constrictive pericarditis are presented, in all of which the ascites was treated by the insertion of the button. The rationale for the use of the button is purely to obviate repeated abdominal paracenteses. Its main advantage over previous surgical measures for the relief of ascites is its simplicity of application. An additional value is that it returns to the patient his own ascitic fluid together with its protein content as a constant slow clysis so long as the fluid is formed.

TUBERCULOSIS OF THE GENITOURINARY TRACT AMONG SOLDIERS IN WORLD WAR II*

RICHARD CHUTE, M D †

BOSTON

IN World War II, in the United States Army, all patients with tuberculosis — whether pulmonary or otherwise — were sent either to Fitzsimons General Hospital, Denver, Colorado, or to Bruns General Hospital, Santa Fe, New Mexico. Of the two hospitals the former was considered the senior and more important, since it was older and larger and was a permanent installation. The treatment of tuberculous patients at Fitzsimons General Hospital was typical of that in the majority of cases in the Army, and as chief of the Section of Urology from January to December, 1945, I had the opportunity to observe and treat a good deal of the tuberculosis of the genitourinary tract that occurred in the Army during that period.

The incidence of pulmonary tuberculosis was 0.9 per 1000 soldiers per year before the taking of chest x-ray films prior to separation, but increased to 1.2 per 1000 after these films had been taken. On the basis of the patient population at this hospital, the ratio of occurrence of pulmonary to genitourinary tuberculosis was approximately 33:1 — a yearly incidence of genitourinary tuberculosis of about 0.03 per 1000 soldiers.

Many different races were represented, including the White, Jewish, Negro, American Indian, Mexican, Filipino, Chinese and Eskimo. Seventeen per cent of the patients were Negroes, and there were an appreciable number of American Indians. In view of the higher percentages of these races among the tuberculosis patients than in the Army as a whole, it seems fair to conclude that they are more susceptible than the average soldiers. More than a third of the patients (38 per cent) were from the Army Air Forces, including some flying and some ground personnel. More than half the patients had been overseas, usually for a good many months, in various areas, England, Europe, the Mediterranean, the Pacific, India and Alaska, — and there was no obvious predominance of patients with tuberculosis from any one theater. Most of the patients were not in the youngest Army age group but were a little older, the average age being twenty-eight and a half years. Practically none of them gave a history suggestive of previous tuberculosis, which of course is natural in view of the fact that men with a known history of tuberculosis are not taken into the Army. Also, surprisingly few patients gave a history of tuberculosis in the immediate family or of known exposure to it.

The tuberculosis of the genitourinary tract seen in the soldiers consisted almost entirely of either

renal tuberculosis or tuberculosis of the epididymis, the latter being observed in a ratio of 4:3. Both renal and epididymal tuberculosis, however, frequently occurred in the same soldier, 40 per cent of the renal cases also had tuberculosis of the epididymis, and 30 per cent of the epididymal cases had concomitant renal tuberculosis. The fact that unexpectedly few patients — only about 20 per cent of the total — had demonstrable evidence of either active or inactive pulmonary tuberculosis was quite surprising if one believes in Louis's law "tuberculosis of any part is attended by tuberculosis of the lungs," and that the original focus for tuberculosis of the genitourinary tract is in the lungs. When pulmonary tuberculosis was found, it was more frequently associated with renal tuberculosis than with epididymal tuberculosis, since it occurred in more than a quarter (28 per cent) of the cases of renal tuberculosis and in 1 in 8 (13 per cent) of epididymal tuberculosis. Extrapulmonary manifestations of active tuberculosis did not usually coexist with genitourinary tuberculosis, but when such an association did occur the most frequent concomitant was bone and joint tuberculosis. Also found occasionally were psoas abscess, tuberculosis of cervical lymph nodes, ophthalmic tuberculosis and tuberculosis of the skin.

In almost all patients the renal tuberculosis was discovered in an early stage, — before it had become advanced, — and the lesions characteristic of advanced renal tuberculosis, such as extensive destruction of the kidney, dilated thickened and tortuous ureters, and severe inflammation and ulceration of the bladder, were not observed.

The first symptoms of renal tuberculosis were as a rule mild and occasionally entirely absent, the disease being detected only as a result of a search for the cause of a persistent pyuria. Symptoms usually consisted of mild discomfort in the back — sometimes accompanied by fever — or of somewhat increased urinary frequency. There were few cases in which bladder symptoms were prominent, and cystoscopy rarely showed the bladder to be involved to any appreciable degree. Microscopic pathological examination, however, showed the ureter to be involved to some extent in many of the cases of renal tuberculosis, except the extremely early ones.

In an appreciable number of cases the pyelogram gave evidence that was inconclusive and was suggestive of only cicatricial changes, and in a few cases the pyelograms, both intravenous and retrograde, were not abnormal and gave no help. It was found that retrograde pyelograms gave a better and more

*Presented at a meeting of the New England Section of the American Urological Association, Boston, April 4, 1946.

†Associate visiting urologist, Massachusetts General Hospital, assistant in genitourinary surgery, Harvard Medical School, attending urologist, West Roxbury Veterans Administration Hospital.

endable filling and delineation of the kidney than a venous urogram. On various occasions, when intravenous urograms gave a picture that was either inconclusive or only faintly suggestive, the retrograde pyelogram delineated the kidney much more clearly and completely and sometimes indicated an unsuspected lesion, such as a cavity communicating with a calyx. Therefore, in any case in which the intravenous pyelogram was not quite satisfactory, clear or conclusive, retrograde pyelograms were done. In cases in which both intravenous and retrograde pyelograms were inconclusive it was necessary to depend largely on cultures of the urine, which were found to be absolutely reliable.* In no case did a kidney that had given a positive culture for tuberculosis fail to show the disease on pathological examination after removal, even though the pyelogram had appeared normal. The routine was to culture ureteral specimens of urine from each kidney and also four twenty-four-hour specimens of bladder urine, which were taken simply as a check on the kidney cultures. No case with a positive kidney culture gave negative cultures on the twenty-four-hour urine specimens, if such an event had occurred all cultures would have been repeated. If the results of the cultures did not seem in accordance with the pyelograms, or if there was a question whether or not the supposedly normal kidney was infected, the cultures were repeated before any operation, and in no case was nephrectomy performed until the healthy kidney had been shown to give a negative culture. In comparing the cultures with the stained smears of the urine, it was found that the former were much more accurate. In most cases in which the kidney urine gave a positive culture, which was later corroborated by the finding of tuberculosis in the removed kidney, the stained smears from that kidney were reported negative for tubercle bacilli. Many more positive smears were found in concentrated twenty-four-hour specimens of urine than in kidney specimens obtained at cystoscopy from the same patient, presumably owing to the greater total number of tubercle bacilli. Of course, it is true that the persistence of the person who examines the stained smear and the time at his disposal to examine the slide naturally make a great difference regarding whether or not acid-fast bacilli are found, but the cultures were nevertheless more accurate and sensitive than the smears in detecting tubercle bacilli. When the smears were positive, the cultures were almost always also positive. In a few twenty-four-hour urine specimens with positive smears, however, the cultures were negative, but after repeated smears and cultures the conclusion was reached that the acid-fast bacilli seen on the slide were contaminants, probably smegma bacilli that were indistinguishable on stain. This was another fact suggesting that the culture

was more accurate and reliable than the smear. No guinea-pig inoculations were used at Fitzsimons General Hospital, although they were often used at other Army hospitals and seemed to produce reliable results. Cultures are quite reliable and have the advantage over guinea-pig inoculations in that they are less expensive and much less space is occupied.

Since cultures took two months for completion and occasionally had to be repeated, many patients spent a considerable time in the hospital before operation, but definite knowledge of the status of both kidneys was regarded as absolutely imperative before operation. Also, in view of the facts that tuberculosis is a constitutional disease and that the lesions in the genitourinary tract are secondary to tuberculosis elsewhere in the body, a careful search was made for other foci of infection. Furthermore, in agreement with other workers in this field, it was believed that a sufficiently long, unhurried period of rest and hospitalization both before and after operation improved the patient's general condition and resistance to tuberculosis, so that the results in general were improved, the patients tolerated surgery better, wound healing was better with less tendency to formation of chronic draining sinuses, and surgery was less apt to spread the disease. Unless the disease in the kidney or elsewhere, such as in the lungs, was active enough to make bed rest mandatory, the soldiers were usually not kept on strict bed rest but were allowed to be up some of the time and to partake in restricted activity.

In common with the vast majority of those who have had the opportunity to observe renal tuberculosis, it was believed that the normal kidney does not filter tubercle bacilli from the blood stream to the urine, that tubercle bacilli in the kidney urine obtained by ureteral catheterization denote renal tuberculosis, and that any renal lesion that has progressed so far as any degree of ulceration will not heal spontaneously but will tend to progress despite sanatorium care. Therefore, when the diagnosis of tuberculosis of one kidney had been made and the other kidney was free of disease, nephrectomy was carried out, unless it was contradicted by some complication in the patient's condition. Bilateral renal tuberculosis was exceedingly rare, and was always found in association with active tuberculosis elsewhere in the body. Nephrectomy was not performed in any case of bilateral tuberculosis. If a case of bilateral disease is encountered, however, in which one kidney is badly diseased and destroyed and the other has only a minimal trace of the disease, it is my opinion that nephrectomy of the badly damaged kidney may be advisable. In such a case it is well known that nothing can stop the badly damaged kidney from continuing to deteriorate, and its removal may ameliorate or prevent the development of an excruciatingly painful tuberculous

*The culture medium used was Pettragnani's medium, whose chief constituents are potatoes, milk and eggs.

cystitis and also removes a tuberculous focus from the body. If active pulmonary tuberculosis existed, nephrectomy was not done until the process in the lung was arrested or quiescent to a point where operation was no longer contraindicated. In fact, in such cases, operation was considered desirable to remove a tuberculous focus from the body.

The type of operation done was the ordinary lumbar nephrectomy. The healing was so satisfactory in practically all cases that there seemed to be no object in doing a nephroureterectomy, especially since this procedure would have entailed another incision and put the patient through a more serious operation, increasing the likelihood of morbidity and mortality. In most cases the ureter was simply ligated, carbolized and dropped back into the wound. In some cases in which the ureter was dilated, thickened, tortuous and obviously diseased, it seemed better insurance against chronic sinus formation in the nephrectomy wound to bring the upper end of the remaining ureter out through a tiny stab wound below the main wound. In these soldiers as a group, however, the renal tuberculosis was discovered in an early stage and there were comparatively few of the dilated, thickened and tortuous ureters seen in advanced renal tuberculosis. The wounds were drained with soft rubber drains for twenty-four to forty-eight hours to let out serum, after which the drains were removed, because it was believed that leaving them in might help create a chronic sinus. Most of the nephrectomies were done under spinal anesthesia, which had the advantage that the patients could start taking frequent deep-breathing exercises immediately after operation as a prophylaxis against such pulmonary complications as atelectasis. For the same reason, the patients were made to lie with the operated side down for much of the time for the first twenty-four hours. If the spinal anesthesia wore off during the operation, it was supplemented with a small amount of Pentothal Sodium intravenously. To avoid thrombophlebitis, the patients were allowed out of bed beginning the day after operation, in fact, they occasionally stood up beside the bed on the evening of the operation, to try to void in a more natural position. Despite the fact that the patients continued to get out of bed every day beginning the day after operation, no weak or bulging scars resulted. No wounds broke down, although in 1 case much of the skin incision broke open. There were several cases in which a small draining sinus persisted for weeks. Almost to a man the patients withstood nephrectomy well, and there were no postoperative deaths in the twelve months ending in December, 1945.

Tuberculosis of the epididymis was the most frequent form of genitourinary tuberculosis encountered — 68 per cent of the total. This condition was bilateral in slightly more than a quarter (28 per cent) of the cases and unilateral in the rest. In the cases of epididymal tuberculosis renal tuberculosis was

also present in 30 per cent and pulmonary tuberculosis in 13 per cent.

The first symptom of epididymal tubercle noticed by the soldiers was usually a somewhat full swelling in the affected scrotum that came gradually over a period of weeks or months. Sometimes pain was absent, whereas the pain and swelling occasionally developed rapidly in the course of a few weeks or even a few days. Most soldiers noticed this condition themselves, but in rare cases it was discovered during a routine general physical examination. The diagnosis was made largely on the basis of the physical examination, which characteristically revealed the whole epididymis to be grossly enlarged, hard, nodular and irregular, but not extremely tender. When only the lower pole of the epididymis was grossly diseased there was a typical hard mass at the lower pole in the shape of a large, thick, irregular button. This was practically always adherent to the skin of the scrotum, which was by far the most frequent site for a draining sinus. In a few cases the tuberculous process had definitely spread from the epididymis to involve the testis. The vas deferens was involved in most cases, and was frequently thickened and occasionally beaded. The spermatic vesicle on the diseased side and also the prostate often had indurated, irregular and nodular areas, evidence that they were also involved in the pathological process. In more than a third of the cases (37 per cent) a draining sinus had become established before hospitalization, usually after spontaneous rupture of a scrotal abscess but occasionally following surgical drainage of an abscess. In all cases in which sinuses had once become established spontaneous healing did not take place, and although the sinuses sometimes healed temporarily, they continued to drain until the diseased epididymis — as well as the testis, when it was involved — was finally removed surgically. For this reason, and also to remove foci of tuberculous infection in the body, operation was performed in all these cases.

The technic used was as follows. If a draining sinus existed, a panel of skin was cut so as to surround the sinus with a good margin, and this incision was deepened down to the epididymis so that the panel of skin containing the sinus came away in one bloc when the epididymis was removed. The same procedure was frequently followed when the epididymis was adherent to an area of the scrotal skin, the adherent skin being removed with the epididymis. When the scrotal cavity had been entered the vas deferens was isolated near the epididymis, sectioned with a knife and treated with carbolic acid. The upper end of the vas was freed from the rest of the cord up to the external inguinal ring and then brought out without tension through a tiny stab wound about 2.5 cm lateral to the base of the penis, where it was fixed with a suture so that about 1 cm projected beyond the skin, any excess of vas being resected. The lower part of the vas and

whole epididymis were then dissected en bloc with the testis. As a rule the epididymis was not adherent at the upper pole of the testis, and it was usually not difficult to dissect it free without injuring the main blood supply of the testis, which was near the upper pole. At the lower pole, however, the epididymis was apt to be extremely adherent, so that sharp-knife dissection was almost always necessary to separate it from the testis. Frequently abscesses were broken into during the dissection, but this gross contamination of the wound with tubercular pus did not appear to affect healing adversely. The scrotum was always lined with a soft-rubber wick, to release oozing blood and serum, but this wick was always removed at the end of forty-eight hours, to avoid the creation of chronic sinus in the presence of a disease that notorious for its tendency to sinus formation. In several these wounds healed satisfactorily, and in no case did the scrotal incision break down. But in the great majority of cases drainage via the wick persisted for at least two weeks, and occasionally longer, although in a few cases there was no significant drainage and the wounds healed completely in a few days. In cases in which the drainage tended to persist, heliotherapy was used, which was regarded as a definite aid in the healing process. The projecting exteriorized end of the vas gradually retracted back to the level of the skin, and when drainage ceased it healed over. As might have been expected, the vasa most prone to drain were greatly thickened, contained pus in the lumen and were obviously markedly involved by tuberculosis. The drainage lasted all the way from several days to several months, but the average time was ten to fourteen days and in some cases there was little drainage. As in the nephrectomy cases all patients started getting out of bed the day after operation. Bringing the vas out on the skin through a tiny stab wound is important. Since most of the vasa and many of the seminal vesicles with which they connect are tuberculous, they usually drain moderately. Exteriorizing the end of the vas allows the drainage to discharge on the skin, where it can be taken care of easily and where it can do no harm. Several cases were seen in which epididymectomy for tuberculosis had been performed elsewhere but the upper end of the vas had been allowed to remain inside the scrotum, and in which either a scrotal abscess or a chronic draining sinus in the scrotum had formed, both of which complications could have been avoided by exteriorizing the draining upper end of

the vas at the time of operation. In this group of cases there were no deaths following epididymectomy or epididymo-orchidectomy.

SUMMARY

The incidence of pulmonary to genitourinary tuberculosis among soldiers in the Army seen at Fitzsimons General Hospital in 1945 was approximately 33.1. Negroes and American Indians had a high incidence.

Two main forms seen were renal tuberculosis and tuberculosis of the epididymis, the latter being more frequent in a ratio of 4:3. Both forms occurred in about a third of the cases.

Only about 20 per cent of the soldiers with genitourinary tuberculosis had demonstrable pulmonary tuberculosis, which was found twice as often in association with renal as with epididymal tuberculosis.

In these soldiers, since the renal tuberculosis was discovered in an early stage the first symptoms were mild — backache, some frequency and symptomless pyuria.

Retrograde pyelograms were more reliable and informative than intravenous pyelograms, but often all pyelograms were inconclusive and cultures had to be depended on to make the diagnosis of tuberculosis.

Nephrectomy was the treatment for unilateral renal tuberculosis. Soldiers withstood operation well, wound healing was good, and there were no deaths.

Epididymal tuberculosis was bilateral in a quarter of the cases. Scrotal abscess that had ruptured spontaneously, followed by persistently draining sinuses had occurred in more than a third of cases before hospitalization. First symptom was usually gradual, slightly painful swelling of the epididymis, which became large, hard and irregular. Epididymectomy, preserving the blood supply of the testis, was the treatment of choice. The wounds healed well, and there was no mortality. Exteriorizing the upper end of the vas deferens on the skin, so that it can drain there rather than inside the scrotum, is of real value.

The value of a prolonged period of hospital rest both before and after surgery cannot be overestimated. This results in improvement in the patient's general condition and resistance to tuberculosis, so that surgery is better tolerated and is less apt to spread the disease, and wound healing is better, with less tendency for chronic draining sinuses to develop.

The healing was so satisfactory in practically all cases that there seemed to be no object in doing a nephroureterectomy, especially since this procedure would have entailed another incision and put the patient through a more serious operation, increasing the likelihood of morbidity and mortality. In most cases the ureter was simply ligated, carbolyzed and dropped back into the wound. In some cases in which the ureter was dilated, thickened, tortuous and obviously diseased, it seemed better insurance against chronic sinus formation in the nephrectomy wound to bring the upper end of the remaining ureter out through a tiny stab wound below the main wound. In these soldiers as a group, however, the renal tuberculosis was discovered in an early stage and there were comparatively few of the dilated, thickened and tortuous ureters seen in advanced renal tuberculosis. The wounds were drained with soft rubber drains for twenty-four to forty-eight hours to let out serum, after which the drains were removed, because it was believed that leaving them in might help create a chronic sinus. Most of the nephrectomies were done under spinal anesthesia, which had the advantage that the patients could start taking frequent deep-breathing exercises immediately after operation as a prophylaxis against such pulmonary complications as atelectasis. For the same reason, the patients were made to lie with the operated side down for much of the time for the first twenty-four hours. If the spinal anesthesia wore off during the operation, it was supplemented with a small amount of Pentothal Sodium intravenously. To avoid thrombophlebitis, the patients were allowed out of bed beginning the day after operation, in fact, they occasionally stood up beside the bed on the evening of the operation, to try to void in a more natural position. Despite the fact that the patients continued to get out of bed every day beginning the day after operation, no weak or bulging scars resulted. No wounds broke down, although in 1 case much of the skin incision broke open. There were several cases in which a small draining sinus persisted for weeks. Almost to a man the patients withstood nephrectomy well, and there were no postoperative deaths in the twelve months ending in December, 1945.

Tuberculosis of the epididymis was the most frequent form of genitourinary tuberculosis encountered — 68 per cent of the total. This condition was bilateral in slightly more than a quarter (28 per cent) of the cases and unilateral in the rest. In the cases of epididymal tuberculosis renal tuberculosis was

also present in 30 per cent and pulmonaryerculosis in 13 per cent.

The first symptom of epididymal tuberculosis noticed by the soldiers was usually a somewhat full swelling in the affected scrotum that came gradually over a period of weeks or months. Sometimes pain was absent, whereas the pain and swelling occasionally developed rapidly in the course of a few weeks or even a few days. Most soldiers noticed this condition themselves, but in rare cases it was discovered during a routine general physical examination. The diagnosis was made largely on the basis of the physical examination, which characteristically revealed the whole epididymis to be grossly enlarged, hard, nodular and irregular, but extremely tender. When only the lower pole was grossly diseased there was a typical hard nodule at the lower pole in the shape of a large, thick, button-like lump. This was practically always adherent to the skin of the scrotum, which was by far the frequent site for a draining sinus. In a few cases the tuberculous process had definitely spread from the epididymis to involve the testis. The vas deferens was involved in most cases, and was frequently thickened and occasionally beaded. The scrotal vesicle on the diseased side and also the prepuce often had indurated, irregular and nodular areas. This was evidence that they were also involved in the tuberculous process. In more than a third of the cases (37 per cent) a draining sinus had become established before hospitalization, usually after spontaneous rupture of a scrotal abscess but occasionally following surgical drainage of an abscess. In all cases in which sinuses had once become established spontaneous healing did not take place, and although the sinuses sometimes healed temporarily, they continued to drain until the diseased epididymis as well as the testis, when it was involved, was finally removed surgically. For this reason, and to remove foci of tuberculous infection in the body, operation was performed in all these cases.

The technic used was as follows. If a draining sinus existed, a panel of skin was cut so as to surround the sinus with a good margin, and this incision was deepened down to the epididymis so that the panel of skin containing the sinus came away en bloc when the epididymis was removed. The same procedure was frequently followed when the epididymis was adherent to an area of the scrotal skin, the adherent skin being removed with the epididymis. When the scrotal cavity had been entered the vas deferens was isolated near the epididymis, sectioned with a knife and treated with carbolic acid. The upper end of the vas was freed from the rest of the cord up to the external inguinal ring and then brought out without tension through a tiny stab wound about 2.5 cm. lateral to the base of the penis, where it was fixed with a stitch so that about 1 cm. projected beyond the skin, any excised part of vas being resected. The lower part of the vas a

whole epididymis were then dissected en bloc, the testis. As a rule the epididymis was not adherent at the upper pole of the testis, and it was usually not difficult to dissect it free without damaging the main blood supply of the testis, which was near the upper pole. At the lower pole, however, the epididymis was apt to be extremely adherent, so that sharp-knife dissection was almost always necessary to separate it from the testis. Frequently abscesses were broken into during the dissection, but this gross contamination of the wound with tubercular pus did not appear to affect healing adversely. The scrotum was always lined with a soft-rubber wick, to release oozing blood and serum, but this wick was always removed at the end of forty-eight hours, to avoid the creation of chronic sinus in the presence of a disease that is notorious for its tendency to sinus formation. In several of these wounds healed satisfactorily, and in no case did the scrotal incision break down. But in the great majority of cases drainage via the wick did not persist for at least two weeks, and occasionally longer, although in a few cases there was no significant drainage and the wounds healed completely in a few days. In cases in which the drainage tended to persist, heliotherapy was used, which is regarded as a definite aid in the healing process. The projecting exteriorized end of the vas gradually healed back to the level of the skin, and when drainage ceased it healed over. MEDICAL PROGRESS

ACUTE PULMONARY EDEMA, WITH SPECIAL REFERENCE TO EXPERIMENTAL STUDIES*

PHILIP H. HENNEMAN, M.D.†

BALTIMORE

THERE are many discrepancies between clinical observations, modes of therapy and the conventional explanations of the pathogenesis of pulmonary edema. Even superficial consideration reveals the inadequacies of the accepted explanations for this striking syndrome. In 1941 an editorial called attention to this problem, as follows: "Unfortunately as experimental and clinical observations on pulmonary oedema have accumulated it has become clear that the validity of the 'back pressure' or 'left ventricular failure' theory can no longer be considered as established."¹

DEFINITION

Acute pulmonary edema is a syndrome characterized by rapid flooding of the lung alveoli with a serous or serosanguinous fluid, it occurs in a great variety of clinical states, and may rapidly jeopardize the life of the patient.

Its nonspecific name has led to confusion with cardiac asthma, paroxysmal dyspnea or paroxysmal nocturnal dyspnea and chronic pulmonary edema. Cardiac asthma is constantly associated with heart disease, ancillary signs of congestive failure and asthmatic wheezes throughout the chest are usually present. Paroxysmal dyspnea, a closely related symptom of pulmonary congestion found in heart disease, usually appears at night and seems to be the same as cardiac asthma except for the associated bronchial constriction. Chronic pulmonary edema is found in congestive heart failure, pericapillary edema is rather constant, and the condition is rarely characterized by the explosive onset often found in acute pulmonary edema. The hyperneic phases of periodic breathing or Cheyne-Stokes respiration are easily differentiated from the syndrome under consideration, the former's name discloses the differential point involved. In spite of this apparently easy differential diagnosis, acute pulmonary edema is frequently confused both in the literature and clinically, and often must appear in its full-blown state before proper therapy is instituted on the basis of exact diagnosis.

INCIDENCE

Luisada² has reviewed the literature of acute pulmonary edema. There is no satisfactory report on

the incidence, and since patients often do not primarily from this condition, even hospital statistics are not entirely relevant. Such figures greatly needed, however. It is to be hoped that material from both adult and children's hospitals be included in such a review, since heart disease is far less frequent in the latter.

Reid and Teel³ state that pulmonary edema frequent immediate cause of death in cases of convulsive toxemia. Nessa and Rigler,⁴ in 1941, lected a series of 110 post-mortem cases of pulmonary edema in which the average age was fifteen years, with a variation from three months to eighty years. The primary cause of death was carcinoma in 17 cases (16 per cent), vascular accident in 20 (18 per cent), renal disturbance in 8 (7 per cent), cirrhosis and acute degeneration of the liver in 5 (5 per cent), blood dyscrasias in 4 (4 per cent), burns in 4 (4 per cent), septicemia in 4 (4 per cent), miscellaneous in 22 (20 per cent), and various surgical procedures in 26 (24 per cent). The percentage of surgical deaths is particularly notable in this series. Farber⁵ states that acute pulmonary edema is one of the most frequent causes of death found at autopsy in infants and children.

DESCRIPTION OF THE ATTACK

An excellent clinical description has been provided by Sir Thomas Lewis,⁶ as follows:

"The onset may resemble exactly that of the attacks previously described, occurring usually at night and waking the patient from sleep, or it may come in the hours of daylight and wakefulness. The separation of these attacks from those previously described (cardiac asthma) is in fact arbitrary and necessitated only by the relative dryness of the latter and their frequent repetition. In frank pulmonary oedema, while breathlessness is usually urgent from the start, cough is more prominent, and frothy blood-tinged sputum is freely or profusely expectorated. The marching events are often speedy. Cyanosis deepens rapidly, breathing becomes progressively more urgent and less effective. The attack may last at its height for hours. In fatal attacks the pulse becomes steadily weaker until imperceptible, the veins swell, and breathing becomes more gasping, infrequent, and then weaker until it ends."

In a fulminating form, the oedema occurs so rapidly and is so intense that, within a minute or two of crying out in fear, the patient is drowned by the copious blood-tinged fluid that pours into the respiratory passages and overflows frothing from the mouth and nose.

ROENTGENOLOGIC FINDINGS

Nessa and Rigler,⁴ in a discussion of the x-ray picture, refer to the classic butterfly-shaped, faint

*Presented before the Boylston Medical Society, January 16, 1946.

†Formerly, fourth-year student, Harvard Medical School.

symmetrical density of both lungs that is greatest at the hilus and gradually fades out toward the periphery, the apexes and extreme bases are usually clear. The density is homogeneous and obliterates all structural detail in the lung. The fluid collects in groups of alveoli, resulting in an irregular stippled density on the roentgenogram. The edema is often predominantly on one side or entirely unilateral. The condition is distinguished from pulmonary congestion by the presence of enlarged hilar shadows and dilated vessels throughout the lung fields and is further distinguished from massive atelectasis by elevation of the diaphragm, shift of the mediastinum and collapse of the chest wall. Lateral films revealed the congestion and edema to be central and not peripheral, in contrast to the congestion in pneumonia, which is usually peripheral in onset.

PATHOLOGY

Farber⁷ and Moon⁸ described the pathology of pulmonary edema, the former observing the same pathological findings in rabbits following cervical vagotomy. There were massive pulmonary edema, often with bloody fluid, and slight dilatation of the right ventricle and auricle. Pulmonary edema was present in the air and interstitial spaces, the former showed albuminoid casts and linings. The veins, capillaries and lymphatics were tremendously dilated, and the arterioles moderately so. Under direct vision in his experiments, Farber saw first the appearance of red petechiae of consolidation on the surface of the lung, with later enlargement and terminal dilatation of the right side of the heart. These changes in the heart, which have long been a source of controversy, are often explained as a result rather than a cause of the pulmonary edema. Undoubtedly, with such massive edema, obstruction to the flow of blood follows, pulmonary arterial pressure rises,⁹ and dilatation results, for the right side of the heart is working against a greater bed of fluid. Similarly, if a great amount of fluid is rapidly lost into the lungs, one might expect decreased return to the left side of the heart, with consequent decrease in size. Earlier workers sought to explain the dilatation frequently seen by failure of the right side, but it is difficult to understand how such failure could cause congestion of the lungs.

The fluid of pulmonary edema is usually characterized as a plasma filtrate with a high concentration of protein. Blood is found in varying amounts. Renault and de Basch¹⁰ demonstrated the absence of fibrin and inability to clot in pulmonary edema fluid. Pesenco¹¹ reported a vasodilatory effect that he believed to be due to the presence of histamine in large quantities.

PATHOLOGIC PHYSIOLOGY

Several features of the pathologic physiology of acute pulmonary edema are worthy of note.

Vicious circle of anoxia It is an old maxim that anoxia begets anoxia, and this is especially true of the lungs, for with the onset of anoxia there is increased capillary permeability and resultant pulmonary edema. In turn this edema prevents aeration of the alveoli and oxygenation of the blood, promoting and advancing the anoxia and edema. Drinker¹² presents many graphic illustrations of the drastic effect of anoxia on the lung capillaries and comments on their special susceptibility.

Ineffectual drainage Drinker¹² refers to the inadequacy of lymphatic drainage to clear pulmonary exudates and transudates. He points out three routes of removal: the bronchi and trachea, reabsorption and enzymatic digestion and resorption of the smaller molecular compounds.

Rise in venous pressure Many authors mention a rise in venous pressure with attacks of acute pulmonary edema, accepting this as evidence of a failing heart, with so-called "back pressure," and tacitly regarding cardiac failure in an acute and unusual form as the cause of acute pulmonary edema. Schmidt¹³ reports that positive intrathoracic pressures as high as 100 mm of mercury may be obtained during forced expiration, such as that in asthmatic breathing. Such a heightened pressure impedes venous return from the head, leading to dilated neck veins. With the respiratory obstruction of massive edema, dilated neck veins may well represent no more than a heightened intrathoracic pressure during expiration.

Blood-pressure changes Frugoni¹⁴ summarized the literature in 1931 and concluded there was no characteristic change in blood pressure with these attacks. Pulmonary edema of itself may well introduce changes in arterial tension. Schweigk¹⁵ and Parin¹⁶ demonstrated a reflex lowering of systemic arterial pressure, with an increase in pulmonary-artery pressure, that might explain some of the changes seen. Asphyxiation causes first a rise and later a fall in blood pressure, and many of the patients are certainly suffering from asphyxiation. Fishberg¹⁷ states there is a primary fall in blood pressure, followed by a rise, with anoxia. Lambert and Gremels,⁹ in Starling's Laboratory, noted in their experiments on heart-lung preparations that the pulmonary pressure in edema rose to high levels in the absence of cardiac failure.

Dyspnea Since dyspnea is such a prominent part of acute pulmonary edema and related conditions it is advantageous to review this subject by means of Altschule's¹⁸ schematic chart of some of the factors producing dyspnea in congestive failure (Fig. 1). It will be noted that most of the factors here involved are also involved in acute pulmonary edema.

General circulatory changes Subsequent to the onset of pulmonary edema there is a loss of a great quantity of fluid into the lungs, with resultant depletion of the circulating blood volume. The small, rapid, thready pulses noted by clinicians in

the late stages may well represent the onset of true shock. A rise in the hematocrit is frequently seen and is also due to loss of plasma into the alveoli.

Heart-lung preparations Many investigators have observed pulmonary edema in heart-lung preparations but have attached varying significance to the factors involved. Modrakowski,¹⁹ Matsuoka²⁰ and others emphasized the critical levels of the pulmonary arterial or general venous pressures necessary for the appearance of the pulmonary edema. Lambert and Gremels⁹ and Wiggers²¹ considered such pressures to be beyond the physiologic range. Lambert and Gremels⁹ and Newton²² observed that such preparations caused degenerative changes in

anoxemia of pulmonary edema, however, there may be increased venous return and increased cardiac output.²⁵ It is well known that a decreased velocity of peripheral and pulmonary blood flow occurs in patients with congestive failure,²⁶ but systematic investigations of the cardiac output by the newer methods and circulation times in patients with pulmonary edema have not been performed, probably owing to the serious nature of the paroxysms.

The urine There are many references in foreign reports to abnormalities of the urine following attacks of pulmonary edema. Some authors have even claimed that the albuminuria often noted is due

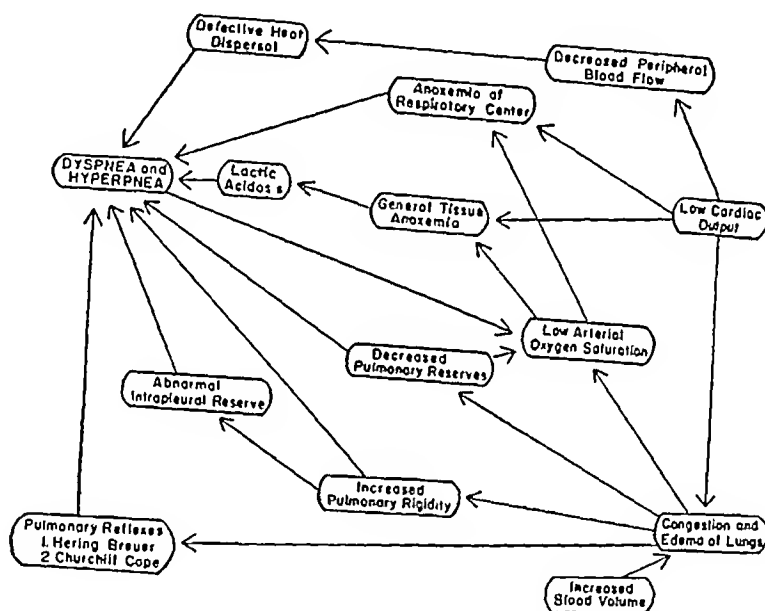

FIGURE 1 Factors in the Dyspnea of Chronic Cardiac Decompensation (Altschule¹⁴)

the intima of the lung capillaries, the edema being attributed principally to injury to the capillary endothelium and the greater permeability thereby produced. The toxic action of old defibrinated blood used in heart-lung circulations is well known. Thus the place of such preparations in pulmonary edema remains uncertain.

Cardiac output and circulation time Harrison,²³ in a review of the studies on cardiac output in cardiac asthma and acute pulmonary edema, states the following: "The idea that cardiac asthma is precipitated by increase in the cardiac output (due to decreased sympathetic activity during sleep, decreased peripheral resistance and hence increased venous return) has not been supported by recent work." In fact, the peripheral circulation has been found to be essentially normal, with no constant changes in cardiac output.²⁴ With the onset of the

to the resorption of albumin from the alveoli after the attack. Frugoni¹⁴ studied this problem and came to the conclusion that any urinary abnormalities merely reflected the underlying disease and were not characteristic of or caused by the attack of acute pulmonary edema.

ETIOLOGY

In the literature no lengthy studies on the incidence of pulmonary edema have been reported, and it is only recently that cases of obviously neurogenic origin have attracted the attention of English and American observers. Cases of cardiovascular disease appear to be predominant, but there are probably more cases of obviously neurogenic origin than has heretofore been appreciated. The variety of cases alone should throw some doubt on a mechanical or cardiac origin of this syndrome.

Cardiovascular diseases Types of cardiovascular diseases presenting this syndrome are as follows: aortic regurgitation and aortitis²⁷⁻³⁰, angina pectoris³⁰, coronary thrombosis^{27 30}, pericarditis^{29, 30}, mitral stenosis²⁹⁻³¹, cardiac failure^{17 31}, hypertension³⁰, wounds of the heart²⁹, and cardiac aneurysm²⁹

Toxic gases^{30, 32 33} Carlisle³³ gives the following list of the industrial gases that cause pulmonary edema: oxides of nitrogen, phosphorus oxychloride, phosphorus pentachloride, phosphorus trichloride, methyl bromide, chlorine, cadmium and dust from certain alkaloids

Drowning^{30, 34} Luisada³⁴ mentions drowning or the penetration of sea water into the upper respiratory passages as a cause of pulmonary edema. It is interesting to note that the lungs of drowning people do not contain sea water but rather the albuminous plasmalike fluid found in other cases of pulmonary edema

Uremia^{17, 27 29 30 35 36} Teisser²⁹ remarks on the frequency of acute pulmonary edema with nephritis and nephrosclerosis and the rarity of the syndrome in pure epithelial nephritis. He mentions gout as another cause, and regards the degree of renal insufficiency as determining the severity of the attack of pulmonary edema. Fishberg¹⁷ believes that the pulmonary edema of renal disease is due to accompanying cardiac weakness

Pregnancy and toxemia of pregnancy^{3, 27 30 35} Reimann³⁰ noted the incidence of pulmonary edema during pregnancy and considered it more frequent in pregnant women than in those with primary cardiac conditions. Reid and Teel,³ who studied this problem extensively, remarked that pulmonary edema is often an immediate cause of death from nonconvulsive toxemia. Among other measures they recommend rapid emptying of the uterus as part of the therapy

Paracentesis^{14, 29 30, 37, 38} Edema has been described following thoracic or abdominal paracentesis. In 1943, Vidal, Fourcade and Girard³⁸ reported that contralateral pulmonary edema was provoked by the creation of an extrapleural pneumothorax.

Central-nervous-system damage or disease^{27 31} The following conditions are cited as causes of pulmonary edema: intracranial hemorrhage^{34, 37 39}, insulin hypoglycemic coma^{40, 41}, brain tumor³⁹, head wounds and trauma^{30 34, 37 39 42-44}, diseases of the peripheral vagus^{39 45}, acute ascending myelitis^{29 30 34, 37 42}, tetanus²⁴, cerebral embolism and thrombosis^{30 37}, vertebral injuries^{37 46}, encephalitis^{37, 42}, polyneuritis and polyradiculitis³⁷, tabes dorsalis^{29 37}, lumbar puncture³⁷, phrenic-nerve crush under local anesthesia⁴⁷, cervical sympathectomy^{46, 48}, laminectomy⁴⁶, and emotional disorders and hysteria^{29 37}. Weissman,³⁹ in 1939, published an interesting series of 686 cases of intracranial hemorrhage with frequent pulmonary edema

In about two thirds of the cases the combined weight of the lungs was over 900 gm, whereas in the control group only 2 per cent of cases showed lungs of this size. Severe edema and congestion of the lungs developed almost immediately after intracranial hemorrhage — that is, within thirty minutes to an hour

Epileptic seizure Several reports list epileptic seizure as a cause of pulmonary edema^{30, 37, 39, 48-51}

Infections^{30, 31} The following infections are regarded as initiating pulmonary edema: acute rheumatic fever^{29, 42}, puerperal fever²⁹, typhoid fever^{29, 42}, measles⁵², scarlet fever⁴², and whooping cough⁵³. The acute circulatory changes described by Freedberg and Altschule⁵⁴ in the various phases of fever may also play a part in the pulmonary edema of infections

Toxic factors Teisser²⁹ reports cases of pulmonary edema in human beings associated with alcoholism and venoms, and in animals following the ingestion of potassium iodide, iodoform, pilocarpine and after intravenous injections of muscarine, chlorine, prussic acid, amyl nitrite and methyl salicylate. Reimann³⁰ lists among the toxic causes alcohol, barbital, iodine, morphine, epinephrine and asphyxiating gases. Bard⁵⁵ reported cases following muscarine poisoning

Miscellaneous causes Newmayer,⁵³ in 1907, reported pulmonary edema during the exertion of coitus and following shocking news. Gibbon and Gibbon⁵⁶ produced pulmonary edema in cats by lobectomy and plasma infusions and warned of clinical repetition of this danger. Other initiating factors are allergy,² thyroid storm,⁵⁷ beriberi⁵⁸ and reflexes from internal organs during operations. Bookhamer and Cullen⁵⁶ reported a case following manipulation of the stomach at operation for Banti's disease. Eason and Karp³⁵ mention angioneurotic edema and distention of abdominal organs. Fisher⁵⁸ reported a case of pulmonary edema, with anesthesia of the entire body as well as respiratory paralysis, following spinal anesthesia using 140 mg of Metycaine in 14 cc of water. Moon⁸ produced edema experimentally by intravenous muscarine, iodine, adrenalin in large amounts, serum in sensitized animals, perfusion of heart-lung preparations with old defibrinated blood, intravenous bile salts, in burns and intestinal obstruction. Most of these cases were observed in animals in shock. Moon⁸ and Reimann³⁰ commented on the frequency of pulmonary edema in shock, especially when death was somewhat delayed. MacKenzie and MacKenzie⁵⁹ found that thiourea and phenyl thiourea rapidly produced pulmonary edema in rats, and Drinker¹² mentions a simple thiourea compound that caused edema regardless of the route of administration. Choisy⁶⁰ reported a case of pulmonary edema with a hypertension apparently elicited by postmenopausal injections of steroids

ANATOMY AND PHYSIOLOGY OF HEART AND LUNGS

Control of Pulmonary Vascular Tone

The problem of pulmonary vascular tone has been disputed for years, and although a definite formulation has not been accepted by all workers the data are quite complete. De Burgh Daly⁶¹ stated that a complete understanding of the nervous mechanisms controlling the lung blood vessels is still lacking, but that workers who have analyzed and summarized the available data generally agree that such control exists. Olkon and Joannides,⁶² in 1930, observed under the microscope caliber changes of the alveolar capillaries in dogs, as well as localized hemorrhages on stress of hyperventilation and convulsions, and attributed their findings to vasomotor control over these vessels. De Burgh Daly and von Euler⁶³ showed that excitation of the stellate ganglion caused pulmonary vasoconstriction, whereas stimulation of the cervical vagi and the cervical or thoracic vagosympathetic nerves produced strong vasoconstriction in some preparations but weak vasodilatation in others. The results of experiments on dogs were summarized as follows:

In view of the finding by these workers that excitation of the thoracic vagosympathetic nerves may augment the mean effective pulmonary arterial pressure 40 per cent, a rise approximating to that obtained by occlusion of the main arterial branch to one lung, it would seem that the vasomotor nerves to the lungs may exert under certain conditions a profound effect on the pulmonary arterial pressure. If such profound changes occur normally the pulmonary vasomotor nerves may maintain a more or less constant pulmonary arterial pressure at all circulation rates, thereby preventing overloading of the right side of the heart.⁶⁴

Adrenalin raises pulmonary arterial pressure and in general constricts pulmonary vessels, although some reports deny such constriction.^{27, 61}

In general, acetyl choline causes vasodilatation of pulmonary vessels. Several workers have shown dilatation of arterioles and constriction of veins with acetyl choline.^{27, 61, 64}

De Burgh Daly and von Euler⁶³ demonstrated in experiments with eserine and atropine that pulmonary vasoconstrictor fibers in the rabbit belonged to the parasympathetic system. Similar pharmacologic evidence was presented by Berry and De Burgh Daly⁶⁵ in support of the presence of parasympathetic vasoconstrictor fibers running in the same nerves, as well as of sympathetic vasoconstrictor and dilator fibers in the thoracic vagosympathetic nerves of dogs, since the constrictor effect following excitation was suppressed or reversed by ergotamine tartrate. Kuré and his associates⁶⁶ described vasoconstrictors of the pulmonary vessels in the dog arising from spinal parasympathetic fibers in the dorsal spinal roots.

Luisada²⁷ raises the question whether vasomotor tone controls permeability of the pulmonary vessels and quotes Krogh's opinion that dilatation and permeability are parallel actions. Heidenhain and

Klemensieviez⁶⁷ claimed experimental proof of such direct vasomotor control of permeability.

In summary it can be said that there is vasomotor control of pulmonary vessels, probably with mixed action by both parasympathetic and orthosympathetic fibers. Adrenalin constricts the pulmonary vessels and acetyl choline dilates arterioles and constricts veins. Vasomotor control of permeability is a possibility.

Nerve Supply to Heart and Lungs

A brief review of the nervous pathways to these organs is included to demonstrate the pathways available for reflexes.

Miller⁶⁸ writes as follows:

The lungs receive their nerve supply from two sources: the vagi and the sympathetic nerves. Each vagus nerve, on reaching the back of the root of the lung, breaks up into numerous branches which, reinforced by fine branches from the second, third, and fourth thoracic ganglia of the sympathetic system, form the pulmonary plexuses. Each plexus gives off fibers which are distributed to the bronchi and pulmonary artery at the hilum. On entering the lung these fibers form two main plexuses which are distributed, one about the main-stem bronchus and its branches, the other about the pulmonary artery and its branches.

Another description of the nervous pathways is given by Karsner.⁶⁹

Larsell⁷⁰ concluded that the plexuses and ganglia of the human lung are in general similar to those described in the dog and rabbit. Afferent nerve endings are found in the bronchi as far as the proximal end of the alveolar ducts, in the atrial walls and in the bands of bronchial muscle, as well as in the adventitia of the pulmonary artery and the perichondrium of the bronchial cartilage plates. Terminations of motor type, which are present in the bronchial muscles and bronchial mucous glands, appear to arise from the nerve cells of the bronchial ganglia. Nerve fibers ending in the smooth muscle of the pulmonary and bronchial arteries originate from the periarterial plexus, which appears to be composed of postganglionic fibers from the upper thoracic sympathetic ganglia. Fibers from the periarterial plexus extend into the parenchyma and form a plexus of delicate nerve fibers on the pulmonary capillaries; terminal fibers end on the capillary walls.^{70, 71} The vagal efferent fibers arise from the dorsal nucleus of the vagus in the medulla and pass via the vagal trunk to be distributed over both lungs, their peripheral ganglia lying over the hilus of the lung. The vagal afferent pathways are again via the vagal trunk to the nodose ganglion lying just below the jugular foramen.²⁷

In 1926 Rasmussen⁷² described the nervous pathways as follows:

The sensory fibers of the vagus enter the upper portion of the medulla oblongata, where some terminate in the immediate neighborhood, while others run downward toward the spinal cord as part of the solitary fasciculus to end in various centers, especially the respiratory center. A few fibers may even go down into the spinal cord as far as the

first cervical segment (Cajal) Freeman in 1925 has also described a bundle of fine fibers as far as the third cervical segment.

The sympathetic supply to the lungs comes from the lateral horns of the spinal medulla via white rami from the second through the sixth thoracic ganglions. Most of the sympathetic fibers come through the stellate ganglion. Apparently the sympathetic supply is also distributed bilaterally to the lungs. There are also afferent pathways through these sympathetic fibers to the stellate ganglion and to the posterior horn cells of the cord via the gray rami.²⁷

Kur⁶⁶ claims to have demonstrated a spinal thoracic parasympathetic center and fibers, and although his work has not yet been confirmed¹³ some of his conclusions are of interest. He states that stimulation of fibers leaving the cord by the dorsal roots causes marked constriction of the pulmonary vessels of the dog, and that the spinal parasympathetic fibers therefore have a vasoconstrictor action on the lung while acting as vasodilators on the skin and viscera generally, the spinal center of the vasoconstrictors for the lung is situated in the thoracic region from the fourth to the eighth segments.

Cardiovascular Reflexes

Farber⁷³ in 1940, reported that rapid intravenous infusions in rabbits produced only moderate vascular congestion but after cervical vagotomy caused acute pulmonary edema.

Cervical vagotomy deprives the animal of the function of the nerve endings in the walls of the venae cavae and the pulmonary veins recently localized by Nonidez. The nerve endings in these locations are responsible for the acceleration of the cardiac rate induced by a rise in the pressure of blood entering the right auricle (the Bainbridge Reflex).

In recent experiments in dogs, Schweig¹⁴ found that branches of the pulmonary artery possess nerve endings responsible for reflex pressosensitivity. This mechanism regulates the cardiac rate and arterial vasomotor tone, an increase in the pressure within the pulmonary arterial system causes reflex slowing of the heart and vasodilatation, lowering of the pressure within the pulmonary arteries is responsible for opposite cardiovascular reactions. These reactions cannot be elicited if the nerve fibers from the pulmonary arteries which connect with the vagus nerves are severed. Schweig¹⁴ expressed the belief that during periods of pulmonary congestion the reflex lowering of the general blood pressure caused by a rise in the pulmonary arterial pressure is accompanied by peripheral and splanchnic vasodilatation, which tends to prevent overloading of the pulmonary circulation. It may be suggested also that at times of temporary increase in the pressure in the pulmonary artery such a mechanism might exert a beneficial influence on the pulmonary circulation by preventing an increase in pressure in the bronchial artery.

(To be concluded)

CASE 32421

PRESENTATION OF CASE

A seventy-eight-year-old retired electrician entered the hospital because of swelling of the legs

Ten months before admission the patient first began to have cramps in the right calf on walking short distances. Soon pains occurred in both legs, increasing in frequency and intensity until four or five months before admission, when they were more or less constant throughout each day. Occasionally the cramps also occurred at night during sleep. Three weeks before admission attacks of nocturnal dyspnea occurred at least once and later three or four times nightly. Associated with the attacks was a slight nonproductive cough. There had been no exertional dyspnea or anginal pain. There had previously been no history suggestive of cardiac difficulty. The patient had slept on two pillows for many years.

Two and a half weeks before admission swelling of the ankles and legs appeared for the first time. The legs were cool and red. Numerous small purple spots developed over the dorsums of both feet and the medial aspects of the calves. The swelling increased rapidly. Two weeks before admission spontaneous drainage of watery fluid from both legs began. The swelling extended slightly above the knee. There was no history of hypertension, headaches, tinnitus or visual disturbances.

Physical examination showed the patient to be moderately orthopneic. The neck veins just above the clavicle were engorged and pulsating in the up-

right position. The heart was enlarged, the border being 12 cm left of the midsternal line in the fifth interspace. The rhythm was irregular, and the rate was 120, with a pulse deficit of 20. No murmurs were heard. There were bilateral fine basal rales and decreased breath sounds, voice sounds and tactile fremitus. The liver edge extended 3 cm below the rib margin. Below the knees there was +++ pitting edema. The skin was tense, red, cool and dripping with moisture. There were purpuric spots and telangiectasis on the medial aspects of both thighs. No arterial pulsations were felt below the femoral vessels. The legs were not tender.

The temperature was 98°F, and the respirations were 20, the blood pressure was 160 systolic, 90 diastolic.

Examination of the blood showed 16 gm of hemoglobin and a white-cell count of 10,000, with 86 per cent neutrophils. A chest film showed moderate bilateral pleural fluid, widened pulmonary vessels and predominantly right-sided cardiac enlargement (Fig 1). An electrocardiogram was interpreted as showing auricular fibrillation, and enlargement and strain of the left side of the heart, without significant coronary disease. The circulation time (Decholin) was 29 seconds (normal, 12 to 18 seconds).

With bed rest and Purodigin the patient's condition improved rapidly, the rales disappeared and the swelling of the legs diminished markedly. The pulse remained irregular at 80 per minute. At 8.30 p m on the fifth hospital day mild, cramping, non-radiating pain suddenly developed in the lower abdomen. There was no nausea or vomiting. Six loose nonbloody bowel movements were passed with moderate but incomplete relief in the first hour after the onset of the abdominal pain. The abdomen was soft and nontender. Peristalsis was normally active, and there was no rebound tenderness. Rectal examination was negative. A stool specimen was guaiac negative. There was no liver or costo-vertebral-angle tenderness. The liver and spleen could not be felt. The lungs were clear. The blood pressure was 150 systolic, 90 diastolic, the pulse was 160 and regular. The temperature was 98°F. The white-cell count was 16,000, with 90 per cent neutrophils. A cardiette examination showed auricular flutter, with a 2:1 block. Six milligrams of morphine

and quinidine was given. There was little change during the night except for progressive apprehension and beginning disorientation. On the sixth hospital day, eleven hours after the onset of the attack, the patient was much worse, and could be roused only with difficulty. The temperature was 100.5°F, the pulse had dropped to 65, the respirations had risen to 40 and the blood pressure had dropped to 90 systolic, 40 diastolic. The white-cell count climbed to 26,000. The abdomen was markedly distended and moderately tender in both lower quadrants. There were no masses or rebound tenderness. Peristalsis was absent. No urine was passed. Twenty

The hemoglobin was slightly high and raises the question of polycythemia, but I assume that it was merely due to the accentuation of cardiac difficulties, with a certain amount of dehydration, and had no further significance. The prothrombin time was also elevated, but I doubt if it was important from the point of view of the final diagnosis.

Up to this point the case has been more or less a routine problem, and we are then presented with the final episode. At the time of this episode, I assume that the resident in charge of the medical wards thought that the patient was probably suffering from acute enteritis, and although a complete and care-

FIGURE 1

hours after the onset of the attack the patient was moribund and in deep shock, with a cold moist skin, an imperceptible blood pressure and Cheyne-Stokes respirations. He stopped breathing twenty-seven hours after the onset of the attack.

DIFFERENTIAL DIAGNOSIS

DR. CLAUDE E. WELCH: This case starts with a typical history of peripheral arteriosclerosis involving the legs. The swelling of the ankles and legs at a later time raises the question of whether the patient developed cardiac decompensation or whether he had a superimposed attack of venous thrombosis. "Two weeks before admission spontaneous drainage of watery fluid from both legs began." This implies the diagnosis of cardiac decompensation with edema, because such an occurrence with primary thrombophlebitis is extremely rare.

ful physical examination was indicated there did not seem to be any tremendous urgency about the case until the following morning. May I point out that if an examination is made immediately after the onset of an intra-abdominal surgical emergency, it may be almost negative and quite misleading. In other words, it takes a few hours for enough signs to develop to make a diagnosis. Hence, a great difference may be noted in the abdomen three hours after the onset of the illness or at the most six hours afterward. In the case under discussion there were progressive apprehension and beginning disorientation during the night. In the morning the patient was obviously a sick man and dying rather rapidly. At that time there was no indication for surgical help, the patient would merely have been speeded on his way.

The differential diagnosis, then, reduces itself to the question, What abdominal catastrophe could produce death in this short period of twenty-seven hours? There are only a few things that need be discussed mesenteric thrombosis, acute pancreatitis, dissecting aneurysm and volvulus. Several of them can be disposed of easily. In the first place, pancreatitis, which can rapidly produce shock and death, can be ruled out because there was no vomiting, all the symptoms were referable to the lower abdomen, and there was no tenderness at any time over the pancreas.

Dissecting aneurysm or some lesion of that type within the abdominal cavity can produce rapid death. Again, the history is unusual for that. The pain usually starts in the chest but later shifts to the abdomen. It would be of interest if we had had a report on the condition of the femoral vessels during the later examinations because if there is a dissecting aneurysm frequently one or both vessels become obliterated as time goes on. Again, with this diagnosis, pain should be steady.

Volvulus of the bowel could conceivably produce death in this short time, but it is unlikely. This would have been the first attack of volvulus—a rare occurrence in a man of seventy-eight. Usually there are repeated attacks before a fatal attack occurs.

By far the most attractive diagnosis is that of mesenteric thrombosis. There is nothing incompatible with that diagnosis. In the first place, the pain came on suddenly and was crampy. Crampy pain is not at all infrequent with mesenteric thrombosis, although the pain is often steady. The diarrhea is suggestive of involvement of the bowel. The physical findings at the onset are often as negative as they were in this case. I might mention that normal peristalsis is a misleading sign. Most of you know that again and again there can be acute inflammation or a vascular lesion in the abdomen with normal peristalsis. In the case under discussion, as time went on, shock developed, the white-cell count rose to 26,000 and evidence of peritoneal irritation appeared. All these signs are typical of mesenteric thrombosis. The fact that no urine was passed can indicate one or two things—either complete block of the renal artery by thrombosis, which is extremely unlikely with mesenteric thrombosis, or, much more probably, that the patient was in a state of shock.

If this was mesenteric thrombosis, what type was it? Could the patient have had an arterial embolus, or was it primary arterial or venous thrombosis? It is a difficult differential diagnosis to make. I might merely say that if venous thrombosis occurs as the primary incident, the symptoms are likely to last for several days before the case is considered a surgical emergency. On the other hand, if the obstruction is arterial in type, it is much more probable that the patient will either die or come to operation rapidly.

I doubt if this was an arterial embolus because the pulse was still irregular and the patient was still fibrillating at the time the pain started. If he had stopped fibrillating or had had other cardiac changes at that time, an embolus would be likelier. I think that this patient died of mesenteric thrombosis that was primary in the arterial system but at the time of autopsy involved both mesenteric arteries and veins.

DR. TRACY B. MALLORY: Do you want to see the x-ray films?

DR. WELCH: I did not know that there were any.

DR. MILFORD D. SCHULZ: I do not believe they contribute anything.

DR. WELCH: They might be of interest, but I should not change the diagnosis.

DR. ALLAN M. BUTLER: What would you have done on the ward? Would you have liked a plain film of the abdomen when the pain started?

DR. WELCH: Later on.

There is an x-ray picture described as being typical of mesenteric thrombosis. The scout film looks like intestinal obstruction running over to the splenic flexure. When a barium enema is given, however, no evidence of obstruction is found.

DR. SCHULZ: The film shows enlargement of the heart, engorgement of the hilar vessels, particularly on the left, and fluid in the pleural sinuses.

DR. LEWIS K. DAHL: I should like to ask Dr. Welch what he would have done if he had been on the ward and made the diagnosis of mesenteric thrombosis.

DR. WELCH: That is a difficult question to answer. In the first place, the man was seventy-eight years old and had to die sometime. I think that the surgeon must seriously consider whether postponing death is necessarily desirable or even justified. We know that this man was old and that in such case the operative mortality for mesenteric thrombosis is 90 per cent. But being a surgeon I should probably have advised operation, realizing that it would probably have killed him but might possibly have saved him temporarily.

CLINICAL DIAGNOSES

Arteriosclerotic heart disease

Cardiac failure

Mesenteric thrombosis

DR. WELCH'S DIAGNOSIS

Mesenteric thrombosis, arterial and venous

ANATOMICAL DIAGNOSES

Embolism, superior mesenteric artery

Arteriosclerosis, generalized, severe

Arteriosclerotic aneurysm of thoracic aorta, with mural thrombosis

Hypertrophy of heart

PATHOLOGICAL DISCUSSION

DR MALLORY The immediate cause of death in case was occlusion of the mesenteric artery. It not due to local thrombosis, however, but to an embolus. The source of the embolus was not in the heart. It was a large fusiform arteriosclerotic aneurysm of the thoracic aorta. I was hoping that Dr Schulz would show that to us.

DR SCHULZ What I took to be part of the left aortic root is the aneurysm.

DR MALLORY The aneurysm measured 13 cm in length. It was partially filled with an adherent, gelatinous clot. The clot found in the superior mesenteric artery was of the same color and consistency as that in the aorta and was not adherent. It would have been if formed locally, I therefore think that we can be reasonably sure that it was an embolus. The other findings were not of any particular significance. There was widespread generalized arteriosclerosis, the heart was slightly hypertrophied, and the majority of the other organs showed only senile atrophy, which would be expected in the age of seventy-eight.

CASE 32422

PRESENTATION OF CASE

A sixty-six-year-old watchman entered the hospital because of painless hematuria.

The patient had his first attack of hematuria three months before entry, when he was taking sulfonamides for an upper respiratory infection. The attack lasted for four days. The patient then remained asymptomatic until three weeks before entry, when he had another entirely spontaneous episode lasting one day during which he passed grossly bloody urine and clots, there was no pain with the bleeding. He was seen at that time in the Out Patient Department, where cystoscopy showed the blood to be coming from the right ureter. An intravenous pyelogram revealed a reduplication of the right urinary passage, with the point of reduplication not demonstrable. One ureter entered the middle and lower calyces, and the other led to the upper calyx. The minor calyces, particularly the lower, were incompletely visualized, and there was a questionable filling defect. The urinary passages on the left side were normal. There was an irregular, filling defect along the floor of the bladder over the region of the prostate, and at least one small diverticulum on the left side of the bladder. The patient had had no other urinary symptoms and passed a good stream. He had had no chills or fever and had recently gained 4 pounds.

Seven years before entry the patient was in another hospital because of a "cavity in the right lower lobe." Healing was apparently spontaneous,

and he was discharged in three weeks. During the following six years he suffered from pain in the right chest whenever he caught cold. He was seen in the Medical Out Patient Department six months before admission, when a chest x-ray film showed increased density in the region of the right apex and first interspace that was interpreted as probably inactive tuberculosis.

Physical examination was negative except for a boggy, nontender prostate, enlarged to about twice the normal size.

The temperature, pulse and respirations were normal. The blood pressure was 140 systolic, 80 diastolic.

Examination of the blood showed a red-cell count of 4,450,000, with 80 per cent hemoglobin, and a white-cell count of 9700. The nonprotein nitrogen was 30 mg and the total protein 6.4 gm per 100 cc, and the chloride 101 milliequiv per liter. The prothrombin time was normal. The urine was light amber and acid, and had a specific gravity of 1.012, it gave a ++ test for albumin, and the sediment contained 20 red cells and 4 white cells per high-power field. A culture and smear were sterile.

An x-ray film of the chest showed no change from the previous examination. A retrograde pyelogram revealed the reduplication on the right to be complete. The lowermost group of calyces were not unusual. In the upper group a filling defect was again seen, and there were two rounded areas measuring about 1.5 cm in diameter each, consistent with nonopaque stones or tumor (Fig. 1). A plain film over the region of the right kidney showed minimal flecks of calcification in the region of the upper pole in, and corresponding to, the location of the mass seen in the pyelogram.

An operation was performed.

DIFFERENTIAL DIAGNOSIS

DR WYLAND F. LEADBETTER I do not know how much sulfonamide this patient was taking or whether he was taking sodium bicarbonate with it. There is a possibility that this therapy had a bearing on the subsequent events, but it is unlikely.

Painless hematuria in the presence of clots, particularly large clots, might be thought to be due to bleeding from the bladder, because bleeding from the kidneys, if massive and with clots in the renal pelvis, is quite apt to produce renal colic. That statement, however, ought not to be taken as a definite rule — simply something to bear in mind.

It is impossible to make a definite diagnosis from the intravenous urograms. The record simply states that the urinary passages on the left were normal. Therefore, we can say that this patient presumably had hematuria coming from the right upper urinary tract, but we do not know whether it came from the upper or lower half of the right kidney.

At cystoscopy there was no mention of a tumor of the bladder. The irregular filling defect, I sup-

pose, was visualized from the cystogram. The fact that there was a diverticulum suggests that there was or had been some obstruction to the lower urinary passage.

The lung cavitation is interesting. It seems unlikely that that was a tuberculous infection. It was possibly a lung abscess that healed. I can not see that it had any bearing on the present situation.

White cells in the urine could be associated with the bleeding and need not be an indicator of infection.

The retrograde pyelogram should be the key to the diagnosis in this case, and we might see the films now.

DR. MILFORD D. SCHULZ: This is a representative film, and the left side appears to be normal.

FIGURE 1

An x-ray film taken six months before admission showed inactive tuberculosis of the right upper lobe. That might have had a bearing on the present illness, but I do not believe that we can do much more than assume that this patient had had active pulmonary tuberculosis at one time.

The lower calyces and ureter on the right seem also to be quite normal, but there is something amiss in the calyx of the upper half. In the duplicated right kidney there is a round, lobulated filling defect that is better seen on the retrograde film.

LEADBETTER Is there any calcification in the area?

R. SCHULZ There is no calcification in that and the ureter leading to the involved calyx normal

R. ALLAN M. BUTLER There is no calcification, does that rule out a stone?

R. SCHULZ No, nor does it rule out tuberculosis

R. BUTLER Is the incompleteness of the filling the right upper half a possible indication of a lesion that is not radio-opaque?

R. SCHULZ It could be a nonopaque stone, blood clot, tumor or granulation tissue — anything that displaces the opaque material in the pelvic calyces

R. LEADBETTER May we see the film that outlines the ureter?

R. SCHULZ There is nothing remarkable about except that it shows the upper third of the ureter, which looks perfectly normal. There is a suggestion of a little more of the lower ureter on the right side, but there is nothing of further interest

DR. LEADBETTER Will you be willing to comment on the cystogram?

DR. SCHULZ The irregularity in the floor of the bladder looks as if it might be due to prostatic enlargement. The diverticulum is probably associated with the irregularities and trabeculations seen throughout the wall of the bladder.

DR. LEADBETTER This illustrates the point that when hematuria is present it is necessary to work the case up completely to determine accurately the site of bleeding and to obtain good pyelograms, if the upper urinary tract is involved. The history in this case was one of short duration, with two episodes of gross hematuria, and I think that we can definitely say that the bleeding came from the right urinary tract. In view of the finding in the upper half of the right kidney, we must assume that the bleeding originated there, although there is no direct statement to that effect. We may assume that there was benign prostatic hyperplasia, which accounts for the changes and the irregularities in the bladder floor and the diverticulum of the bladder.

What was the lesion in the upper pole of the right kidney? The x-ray studies show a definite filling defect, although it is not clearly outlined. The diagnosis seems to rest between tumor, tuberculosis and nonopaque calculi. There is one other point to be noted regarding the filling defect: it does not appear to be free in the pelvis. Whatever the lesion was, it was associated with calyces or with the parenchyma and was not free in the true pelvis. For that reason I should be inclined to rule out the possibility of nonopaque stone. If

we were more critical about this pyelogram we could say that this shadow represents the upper calyx, and these, the lower and midcalyces in the upper portion of the kidney. There appears to be dye extending up about the filling defect and possibly representing infiltration of dye into the kidney substance. This is somewhat suggestive of renal tuberculosis. On the other hand, we are dealing with an illness of short duration and the ureter appears normal. In renal tuberculosis the ureter usually shows characteristic changes, and I am inclined to think that one is obligated to make a diagnosis of renal tumor.

DR. BENJAMIN CASTLEMAN Would the shadow be round if it were due to tuberculosis?

DR. LEADBETTER Not usually, but I think one can find almost anything in a cavitation due to tuberculosis. On the basis of the history and the x-ray findings I believe that one must make a diagnosis of tumor involving the upper pole of the kidney. It is necessary to differentiate papillary tumor of the pelvis and renal-cell carcinoma — that is, a tumor originating in the renal parenchyma. It is difficult to decide in this case. The outline of the kidney is not definite in the films, but it is fairly obvious that there is no enlargement of the upper pole of the kidney, and it is probably better to make a diagnosis of papillary carcinoma of the renal pelvis, involving the upper half of the right kidney, benign prostatic hyperplasia and, in addition, inactive tuberculosis of the right upper lobe of the lung.

DR. JAMES B. TOWNSEND How often will tuberculosis reveal itself as painless hematuria?

DR. LEADBETTER Quite often, it is one of the most frequent signs of early renal tuberculosis. On the basis of the pyelogram showing the essentially normal ureter it is difficult to make a diagnosis of renal tuberculosis.

DR. TOWNSEND I suppose that efforts were made to do guinea-pig inoculation.

DR. CASTLEMAN I do not believe that they waited that long.

DR. BUTLER This summary does not tell anything about what was found in the urine by ureteral catheters at the retrograde cystoscopic examination. With catheters up the two ureters on the side where disease was suspected and with catheters up the ureter on the side where no disease was suspected, one had a wonderful opportunity to see what kind of urine was coming from each portion of the kidney. Was any such information obtained?

DR. CASTLEMAN Yes, the material was both cultured and injected into a guinea pig.

CLINICAL DIAGNOSIS

Tumor, upper pole of right kidney

DR LEADBETTER'S DIAGNOSES

Papillary tumor, right kidney pelvis, involving
upper half of double pelvis
Benign prostatic hyperplasia

ANATOMICAL DIAGNOSIS

Papillary carcinoma (Grade II A), involving
upper half of bifid pelvis

PATHOLOGICAL DISCUSSION

DR CASTLEMAN At operation the lesion proved to be a papillary carcinoma, which was graded as II A. As Dr Leadbetter predicted, it was attached to the pelvis and extended into the calyx for a short distance. The ureter was removed at the same time because papillary tumor was suspected. The patient made an uneventful convalescence and was seen a month or two later.

DR LEADBETTER Was the whole kidney removed?

DR CASTLEMAN The entire kidney was removed, the lower calyces showed petechial hemorrhage—I assume from operative trauma. There was nothing in the lower half.

DR LEADBETTER I think it would be possible to remove only the upper half if one could be sure of the diagnosis, and I think that if one could visualize the pelvis it might be possible to make the diagnosis.

DR B. T. TOWERY Were there any ureteral implants?

DR CASTLEMAN No.

DR BUTLER Would it not have been an advantage to take a lateral film at the time of either the intravenous or retrograde pyelograms?

DR SCHULZ I do not know about this case, but lateral films taken at the time of retrograde pyelography are often helpful, especially in the demonstration of tumor.

DR BUTLER That is why I thought that when the possibility of tumor is suspected it would be justified.

SALVATION ARMY LOOKS AHEAD

THE Salvation Army was founded in London in 1864 by William Booth to carry out "the fundamental purpose of taking the Gospel to those who need it but will not seek it." After eighty-two years this evangelistic organization, functioning as the world's greatest system of social services, carries on its work and has its headquarters in every country on the face of the globe. It is infinite in its capacity for mercy, its doors are closed to no one, it works in its own centers and in its hospitals, it finds room for its services in the home and in the street, in the church and in the prison cell.

This month the Salvation Army of Greater Boston is asking for a million dollars. The sum is greater than its usual request because, in addition to its

customary and postwar services, it must have \$149,000 for remodeling of five corps centers and \$375,000 for a new Evangeline Booth Home and Hospital.

The Evangeline Booth Home and Hospital of Boston, one of thirty-five similar institutions operated by the Salvation Army in this country, was opened as a home in Dorchester in 1892. In 1900 it moved to larger quarters, and the hospital department was established, twenty years later, when it entered its present quarters on West Newton Street, the hospital department was separated from the home department and reorganized as a regular maternity hospital equipped to receive patients of the medical staff.

The home cares for unwed mothers regardless of multiparity, the hospital, in which 764 babies were delivered in 1945, is an obstetric teaching unit of Tufts College Medical School, approved by the American Medical Association and the American College of Surgeons. It also conducts a training school for attendant nurses. During the war the hospital was made available to medical personnel of the United States Coast Guard for the delivery of Coast Guard wives.

A general improvement in hospital standards combined with a desire to give increased and better service has forced the Evangeline Booth Home and Hospital to the decision to abandon its present inadequate quarters. It now needs a lying-in hospital of eighty to a hundred beds, with a separate building for the home department, and is asking the public to provide funds to fill this need, even in a year when larger hospitals are experiencing growing pains and are expressing their own needs for expansion. It may be taken for granted that the people of Greater Boston, among their other commitments, will continue to support this essential charity.

RADIOACTIVE IODINE IN THE TREATMENT OF THYROTOXICOSIS

AMONG the recent significant contributions of physics to medicine are studies with radioactive iodine. Dr. Saul Hertz, working in collaboration with Drs. Arthur Roberts, Robley Evans, William Salter and others, utilized this isotope in studying some fundamental mechanisms of function of the thyroid gland, especially those concerned with

iodine metabolism In 1942, Hertz and Roberts,¹ and also Hamilton and Lawrence,² rendered preliminary reports of the effects of therapy with radioactive iodine in the treatment of thyrotoxicosis The results encouraged an extension of the studies by Hertz and Roberts³ On the basis of these observations, Chapman and Evans⁴ were prompted to use larger doses of radioactive iodine than previously had been used in thyrotoxic patients

The basis for such therapy arises from the fact that, since in untreated hyperthyroidism the thyroid gland can take up as much as 80 per cent of a small dose (less than 2 mg) of iodide within a few hours after its administration, it is possible to obtain concentrated irradiation at the site desired without undue exposure of other tissues Although the total number of patients treated with radioactive iodine is relatively small, the results of this type of treatment appear encouraging Hertz and Roberts³ report that, in 29 uninodized patients with hyperthyroidism whose goiters weighed from 60 to 75 gm, radioactive iodine in doses of 5 to 25 millicuries cured the disease in about 80 per cent Chapman and Evans⁴ observed that, in 22 patients with hyperthyroidism whom they treated with larger amounts (14 to 52 millicuries) of radioactive iodine, 14 responded well to the single dose Three were given two doses, and 5 were given three doses, and as a rule, the subsequent doses were larger than the first one Four patients later developed myxedema, and 2 had a persistence of thyrotoxicosis following treatment, although the disease became less intense

The chief problem in the use of radioactive iodine is to determine the optimal dose The amount required depends on the amount of iodine in the body, the size of the thyroid gland, the nature of the pathologic changes in the gland and many other conditions Inability to estimate these factors accurately makes it more difficult to select the proper dose than it is for the surgeon to decide how much of the thyroid tissue should be removed In either instance, only a slight difference in the number of cells that are permitted to live may result in a persistence of the thyrotoxicosis or the development of myxedema It appears wise to use a minimal dose of radioactive iodine, since additional doses can be given if needed, with excessive therapy some patients may develop permanent myxedema Few

other ill effects from the use of radioactive iodine therapy have been observed Occasional patients have had transient reactions resembling roentgen-ray sickness Whether this type of treatment predisposes to the development of cancer or whether structural damages will subsequently occur in other tissues remains to be ascertained

The extent of usefulness of this form of therapy has not been determined In certain complicated cases it is unquestionably the treatment of choice Moreover, it appears to be useful in some patients who have been unsuccessfully treated with thiouracils and in those who have not obtained good results after having been subjected to surgical treatment Indeed, it is possible that this form of therapy may become the one of choice in the majority of patients with thyrotoxicosis, but this can be established only on the basis of the findings in extended investigative studies

SUBACUTE BACTERIAL ENDOCARDITIS*

A Report of Two Cases Successfully Treated with Penicillin

BENEDICT F MASSELL, M D,† AND T DUCKETT JONES, M D ‡

With the Technical Assistance of Mary Meyeserian

BOSTON

THE medical literature contains reports of many cases of subacute bacterial endocarditis treated with penicillin.¹⁻¹⁴ Nevertheless, we are prompted to contribute reports of 2 additional cases. In the first place, all carefully studied cases treated with penicillin should be reported irrespective of their therapeutic outcome,[§] so that by the accumulation of data on large numbers of cases, it will be possible to evaluate adequately the various aspects of this remarkable treatment and to explain the reasons for failure, which still occurs in about 25 to 30 per cent of cases. Secondly, certain features of these 2 cases show interesting contrasts and comparisons. Finally, the penicillin resistance of the *Streptococcus viridans* isolated from the blood in one of the cases was apparently greater than that of the originally isolated causative organism responsible for any other successfully treated case reported so far in the medical literature.⁶⁻¹⁴

CASE 1. G. T. (H. G. S. 6465), a 16-year-old girl, suffered her only definite attack of rheumatic fever at the age of 8 years. During this episode she was treated at the House of the Good Samaritan, and later she was examined periodically in the Out-Patient Department of the Children's Hospital and in the Rheumatic-Fever Clinic of the Massachusetts General Hospital. From the time of discharge from the House of the Good Samaritan until the onset of her last illness she remained essentially well except for occasional nosebleeds and colds. There was never any clinical evidence of acute rheumatic fever, and the blood sedimentation rate remained normal.

The present illness began on June 13, 1944, when the patient went swimming. Soon after arriving home, she had a chill. Chills continued off and on for 2 or 3 days, and migratory joint pains developed. Pains in the muscles of the right upper arm also occurred. There was no history of tooth extraction or other dental work and no respiratory infection prior to the onset of this illness.

On July 20 examination revealed an oral temperature of 103.2°F. The patient appeared thin and pale. The heart was borderline in size, the apex impulse being about in the midclavicular line. There was a loud systolic murmur at the

mitral area. There were no diastolic murmurs. There were no petechiae, but the spleen was easily palpable. Because of the enlarged spleen, subacute bacterial endocarditis was suspected.

Because of an unavoidable delay the patient was not admitted to the House of the Good Samaritan until August 25. During the 1st week at the hospital she was obviously extremely ill. The rectal temperature reached daily peaks of 102.5 to 104.5°F. At times she was lethargic, and sometimes she was delirious. There was moderate pallor. Several tender red spots appeared from time to time over the tips of the fingers and toes. The heart was of borderline size, and the rhythm was regular. The heart rate was rapid and varied from 110 to 140 per minute. There was a loud, widely transmitted, mitral systolic murmur. There were no diastolic murmurs. The abdomen was examined with difficulty because of marked tenderness and spasm in the left upper quadrant. After a few days the spasm lessened, and the spleen was definitely felt. The electrocardiogram was essentially normal except for sinus tachycardia. The PR interval was 0.16 second. The corrected sedimentation rate (Rourke-Ernstene method) ranged between 1.2 and 1.5 mm per minute.

Examination of the blood showed a red-cell count of 3,500,000, with a hemoglobin (photoelectric) of 9.4 gm., and a white-cell count varying from 9000 to 12,000, with 60 per cent neutrophils, 28 per cent lymphocytes, 8 per cent monocytes and 4 per cent eosinophils. The hematocrit reading was 33. The antistreptolysin titer was 125 units. The centrifuged sediment of a single urine specimen showed 5 red cells per high-power field, otherwise numerous urine specimens were negative. The specific gravity ranged from 1.017 to 1.030. Five successive daily blood cultures beginning on August 26 were positive for *Streptococcus viridans*. The organism isolated from these cultures was inhibited in vitro by as little as 0.02 unit of penicillin per cubic centimeter, even a heavy inoculum was inhibited by 0.06 unit.

Penicillin therapy was started on August 31. Intramuscular injections of 37,500 units were given every 3 hours, making a total of 300,000 units every 24 hours. This treatment was continued for 14 days. On September 14, the dose was reduced to 12,500 units intramuscularly every 3 hours, totaling 100,000 units every 24 hours. This reduced dosage was continued for 10 days, when the penicillin therapy was discontinued. During the 24 days of treatment the patient received a total of 5,000,000 units of penicillin. Penicillin blood levels were determined on several occasions on specimens taken 3 hours after the previous injection and just prior to the next injection. On all these occasions the concentration was less than 0.06 unit per cubic centimeter of serum.

The response to penicillin therapy was dramatic. Within 24 hours of the first injection the fever lessened, and the downward trend continued until September 6, when the rectal temperature failed to rise above 100°F. Thereafter the temperature remained normal except for an unexplained period in which the rectal temperature reached 102.5°F. This

§No case of subacute bacterial endocarditis has been unsuccessfully treated with penicillin at this hospital.

febrile episode began on September 15, the day after the 24-hour penicillin dosage had been reduced from 300,000 to 100,000 units, but subsided within 3 days, and thereafter the rectal temperature remained well under 100°F. The patient began to feel better almost immediately after treatment was begun, and her general appearance improved rapidly. The tenderness in the left upper quadrant of the abdomen soon disappeared, but the spleen remained readily palpable until January 23, 1945. Thereafter it could be felt only occasionally just below the left costal margin. The frequency with which small, tender, red spots occurred on the fingers and toes lessened noticeably by September 13, 1944. Occasional spots continued to appear, however, as long as 3 months after the treatment was discontinued.

The corrected sedimentation rate gradually lessened but did not fall within the upper normal limit of 0.4 mm per minute until October 23, after which it remained well within normal limits. The anemia likewise improved, by November 13, the hematocrit reading was 43. The first blood culture after the onset of therapy was taken on September 2 and was sterile. Seven additional cultures during the course of penicillin injections and 32 others after termination of treatment were also sterile.

After discharge from the ward on February 11, the patient was examined at intervals of 1 or 2 months at the Follow-up Clinic and was last seen on September 25, 1946. During this entire period she was feeling extremely well, attending school and leading an essentially normal life. Physical examination remained entirely negative except for the cardiac findings, which had not changed. The corrected sedimentation rate was found to be well within normal limits (less than 0.4 mm per minute), and the blood cultures remained sterile. During the total follow-up period of 24 months since discontinuation of therapy, there was a total of forty-four sterile blood cultures.

CASE 2. M. A. (HGS 4432), a 27-year-old woman, was admitted to the House of the Good Samaritan for the first time on March 10, 1927, when she was 8 years old, during her only definite attack of rheumatic fever. Following discharge, she was entirely well and was able to lead a physically active life. She was examined on occasion in the Out-Patient Department of the Boston City Hospital until October 10, 1939. Thereafter follow-up examinations were continued at intervals at the House of the Good Samaritan clinic. On December 2, 1943, the heart was described as borderline in size, the apex impulse being in the 5th intercostal space 7.5 cm. to the left of the midsternal line and just about in the midclavicular line. The rhythm was regular. There was a fairly loud (Grade 3), somewhat harsh, systolic murmur maximum at the apex, where the mitral 1st sound was masked. There were no definite diastolic murmurs.

In May, 1944, without any preceding respiratory infection, tooth extraction or other unusual event, the patient began to feel tired and developed migratory joint pains. In spite of these symptoms she did not remain in bed for any long period until July 1, when the left ankle became swollen and so painful that she could not walk. About a week later she had lower abdominal pain and for the first time noticed fever, the temperature reaching 102°F (oral). Within a few days these symptoms subsided, but pain in the left buttock and in the left side of the chest soon developed. The chest pain was aggravated by deep breathing. An x-ray film revealed no abnormalities. Mild fever returned and continued in a variable fashion thereafter.

Examination of the patient at home on August 29 revealed an oral temperature of 99.6°F. Three small, nontender red spots and a tender area of purplish discoloration were seen on the extremities. The cardiac findings were essentially the same as those described at the last previous clinic visit on December 2.

A diagnosis of probable subacute bacterial endocarditis was made, and the patient was admitted to the House of the Good Samaritan on September 5. For a period of 23 days—from September 5 to September 28—during which therapy was withheld so that adequate observations could be made, the patient felt fairly well and did not appear very ill. There was a low-grade fever, the daily maximum rectal temperature varying from 100.2 to 101.0°F. Several petechiae appeared during this period. On the morning of September 28, prior to the initiation of therapy, a painful, tender, purplish discoloration, several centimeters in diameter, appeared over the 4th toe of the left foot. At no time could the spleen be felt.

The electrocardiogram was normal and had a PR interval of 0.14 second. The corrected sedimentation rate varied from 0.55 to 0.92 mm per minute. Examination of the blood showed a red-cell count of 3,800,000, with a hemoglobin (photoelectric) of 10.2 gm., and a white-cell count varying from 4700 to 8000, with 67 per cent neutrophils, 29 per cent lymphocytes, 1 per cent endothelial cells and 3 per cent eosinophils. The hematocrit reading varied from 31 to 33. The antistreptolysin titer was 200 units. Eight urine specimens were essentially negative and showed no evidence of microscopic hematuria, the specific gravity varied from 1.017 to 1.024.

Ten consecutive blood cultures taken prior to therapy consistently gave a pure growth of *Str. viridans*. In vitro studies showed that inhibition of growth of this organism required at least 0.40 unit of penicillin per cubic centimeter. With even high concentrations of penicillin, complete or nearly complete sterility could be obtained only if a highly diluted culture was used for the inoculum.

Penicillin therapy was begun on September 28. It was obvious from the in vitro studies that the causative organism was relatively resistant to penicillin and that, to obtain adequate blood levels, larger amounts of penicillin than had been customary at that time would be necessary. For the purpose of obtaining information concerning the relation of blood concentration to dosage, however, an initial daily dose of 240,000 units was given, and this was gradually increased to a maximum of 960,000 units by October 5. During these first 8 days of therapy the penicillin was given intramuscularly every hour in divided doses. On October 6 the method of administration was changed to constant intramuscular drip. For 24 hours, 600,000 units of penicillin were given in this way, and thereafter 960,000 units were given every 14 hours until the medication was discontinued on October 12. The total duration of penicillin therapy was 14 days, and the total amount of penicillin administered was 10,000,000 units. Table 1 presents the details of the therapy and the penicillin

TABLE 1. Method of Administration, Dosage and Serum Concentration of Penicillin in Case 2

DATE	ADMINISTRATION BY HOURLY INTRAMUSCULAR INJECTION			ADMINISTRATION BY INTRAMUSCULAR DRIP	
	DOSE	24-HOUR DOSAGE	SERUM CONCENTRATION	24-HOUR DOSAGE	SERUM CONCENTRATION
	units	units	units per cc	units	units per cc
9/28-9/29	10,000	240,000	0.10		
9/29-9/30	15,000	360,000	0.16

concentrations in the serum of blood collected either 45 minutes after an intramuscular injection or during constant intramuscular administration. Following the discontinuation of penicillin therapy, the patient was kept under observation in the hospital for 10 weeks until discharge on December 24.

Within 48 hours after the initiation of penicillin therapy, the rectal temperature failed to rise above 100°F and thereafter remained within normal limits. There were no further symptoms, and the patient remained entirely free of symptoms. One small, tender, red spot appeared on the tip of the left little finger on October 5, but no evidence of emboli occurred thereafter. The corrected sedimentation rate dropped to 0.39 mm per minute on October 23 or 25 days after the onset of therapy, and subsequently remained well within normal limits. A blood culture on September 29, taken 1 hour after the last previous intramuscular injection of 10,000 units of penicillin, was still positive for *Str. viridans*.

another culture on September 30, taken 1 hour after previous injection of 15,000 units, was likewise positive. The next ten consecutive cultures taken during therapy, however, failed to show streptococci. From the time the therapy was discontinued on October 12 until the time the patient was discharged on December 24, fourteen additional negative cultures were obtained.

Following discharge from the hospital the patient was examined every 1 or 2 months in the Follow-up Clinic. She remained entirely symptom free and, when last seen on October 9, 1946, was leading a normal active life. The radiologic findings remained essentially the same as those described above. Otherwise, physical examination revealed no abnormalities. At all visits the corrected sedimentation rate was well within normal limits and the blood cultures showed no growth. During a total follow-up period of 24 months since discontinuation of therapy, twenty-seven consecutive blood cultures were negative.

DISCUSSION

The clinical backgrounds in these cases were rather similar. Both patients were relatively young women who had developed rheumatic heart disease following a single attack of rheumatic fever early in childhood, both had been observed at the House of the Good Samaritan during the original attacks of rheumatic fever, and both had been examined at intervals thereafter in the clinics of various hospitals. In both cases the valvular lesion was only that of mitral regurgitation, and the heart was of normal size or slightly enlarged. Until the onset of the bacterial infection both patients had been physically active and able to lead normal lives. In neither case could a history be elicited of preceding dental work or respiratory infection.

The clinical course of the bacterial endocarditis, however, was not the same for these patients. The illness in Case 1 began rather suddenly with a chill about two months before admission. From the onset until the effect of penicillin therapy the patient was acutely ill, with a high fever and a rapid heart rate. On admission to the House of the Good Samaritan, she was at times lethargic and at other times delirious. On the other hand, the illness in Case 2 began rather insidiously about four months before admission to the hospital. The patient had persistent symptoms, but at no time did she have a high fever or seem acutely ill. The serum antistreptolysin titers, as might be expected, were low in both cases.

The organisms isolated from both patients were classified as *Str viridans* on the basis of the appearance of their colonies on 5 per cent horse-blood agar plates. Serums for Lancefield grouping were not available in the laboratory at that time, and no other attempts were made to subclassify the strains.

The in vitro behavior of the organisms in the presence of penicillin was of particular interest. The streptococcus isolated in Case 1, in which the patient was acutely ill, was found to be highly susceptible to penicillin. Growth in broth was prevented by as little as 0.02 units per cubic centimeter, and in the presence of concentrations of penicillin slightly in excess of this even a heavy inoculum of the organisms could be completely or nearly completely sterilized within twenty-four hours. In contrast, the

strain isolated in Case 2, in which the patient was mildly ill, was relatively resistant to penicillin. To prevent growth of the bacteria in broth it was necessary to have a concentration of 0.40 units of penicillin per cubic centimeter. Furthermore, the rate at which the organisms were killed even by an excess of penicillin was considerably slower with the strain in Case 2 than with that in Case 1. Thus, when penicillin-sensitivity tests were performed on the strain in the former, sterilization could be completely or nearly completely effected only if a relatively small inoculum was used. If the inoculum contained more than 20,000 organisms per cubic centimeter, sterilization could not be produced by even 100 units of penicillin, and after twenty-four hours of incubation numerous live organisms were still present. Further details and discussion of the in vitro behavior of these strains are included in a report published elsewhere.¹⁵

The patient in Case 1 was cured relatively easily with penicillin in moderate dosage given by intermittent intramuscular injections every three hours. This favorable result is what might have been expected from the knowledge of the high penicillin sensitivity of the causative organism. The persistence of small red spots for a period of sixteen weeks is of interest.

The excellent response of the patient in Case 2 to penicillin is more surprising. Even though she was clinically not acutely ill, the disease had been present for at least four months prior to the initiation of therapy, and as already pointed out, the infection was caused by an organism whose bacteriostatic sensitivity to penicillin was relatively poor in comparison to that of organisms isolated in most cases of subacute bacterial endocarditis. That a cure was actually obtained was probably due, at least in large part, to the fact that a high penicillin concentration in the blood was maintained almost constantly throughout the period of treatment. Concentrations above the bacteriostatic sensitivity level of 0.40 unit were present for most of the time after the first four days, and for a period of five or six days the serum concentration was at a level equal to nearly twice the bacteriostatic sensitivity of the organism.

Another interesting feature in Case 2 was the successful outcome after treatment for only two weeks. Although not necessarily contradictory, this result is particularly worthy of note in view of the opinion recently expressed by Bloomfield and Halpern¹² that penicillin therapy should be continued for at least two months.

There can be no doubt that these 2 cases represent true cures of subacute bacterial endocarditis. The diagnosis was firmly established on both clinical and bacteriologic grounds before therapy was instituted. Both patients had fever and multiple evidences of emboli, as well as repeated and consistently positive blood cultures for *Str viridans*. Both patients responded promptly to therapy. All evidences

of inflammation, including the sedimentation rate, and all embolic phenomena eventually disappeared. Numerous blood cultures during and after treatment continued to be negative. Subsequent to discharge from the hospital the patients were examined every one or two months and were found to be clinically free from disease. Furthermore, the blood sedimentation rates were normal, and the blood cultures were negative at every clinic visit. The total follow-up since discontinuation of the penicillin therapy was twenty-four months for both patients and both were leading completely normal physically active lives.

SUMMARY

Reports are presented of 2 cases in which the patients were cured of subacute bacterial endocarditis by penicillin therapy.

The penicillin resistance of the originally isolated causative organism in one case was greater than that of any other successfully treated case that has been reported in the medical literature.

The correlation of the clinical picture with the penicillin sensitivity of the causative organism is of interest: one patient was extremely ill, and the causative organism was extremely sensitive to penicillin, and the other was mildly ill, and the causative organism was relatively resistant to penicillin.

In one case a cure was obtained after only two weeks of penicillin therapy.

HEMOSTASIS BY THROMBIN AND FIBRIN FOAM IN SUPRAPUBIC PROSTATECTOMY*

An Analysis of 40 Cases

WILLIAM C. QUINBY, M.D.†

BOSTON

THE operative cure of the patient suffering from prostatic obstruction involves three major problems — control of renal function and disordered water balance, control of infection and control of hemorrhage at operation and subsequently.

Dehydration, which is often present in prostatic obstruction, has recently been clearly demonstrated to be responsive to various forms of parenteral fluid therapy based on the chemical determination of the blood electrolytes. A proper acid-base equilibrium of the blood and tissue fluids, which is well recognized as a prerequisite to the successful outcome of any major surgical operation, is especially necessary before prostatectomy. The skillful administration of water, plasma and saline and glucose solutions accordingly plays an important role in successful therapy, the details of this aspect of the treatment of prostatism were presented by Simeone¹ in 1941.

Many of the less severe degrees of urinary infection can be allayed with the aid of a urinary antiseptic such as sulfadiazine. Of equal or greater value is the prevention of infection by avoiding, whenever possible, the use of the indwelling urethral catheter, for the urethra is known to be a constant source of bacteria that rapidly increase in number and virulence owing to the inevitable trauma of an indwelling catheter. Therefore, when drainage of the bladder for longer than a day or two before operation has been necessary, it has been the practice in this clinic to introduce a suprapubic catheter through a trocar or so-called "punch." This procedure causes no discomfort, and the bladder can easily be kept aseptic by the use of a closed system connecting the catheter with the drainage bottle. Austen's² report gives the details of the punch method of bladder drainage.

The most recent advances in prostatic surgery relate to the control of hemorrhage at operation and subsequently. This problem has long been found difficult, and many devices have been applied to its solution. Packing around an indwelling catheter, ligation of bleeding points or coagulation by the high-frequency electric current and, especially in recent times, the pressure exerted by a

distensible rubber bag (Pilcher) have been used with varying degrees of success. The packing and pressure-bag methods, even if efficient in controlling bleeding, almost always cause an extreme degree of vesical discomfort and tenesmus that makes the day or two after operation uncomfortable and requires heavy sedation. The electrocoagulation or actual ligation of bleeding vessels frequently fails to bring about really adequate hemostasis, because the actual bleeding points deep in the prostatic cavity are difficult to reach and identify.

The use of a coagulant that is normally a factor in the production of a blood clot — namely, thrombin — remains to be explored. Its action in converting soluble fibrinogen into insoluble fibrin can be considered the fundamental reaction in the coagulation of the blood.³ Until recently, however, thrombin was difficult to isolate in a sufficiently concentrated form to be of value in producing a firm and adherent clot over a bleeding surface. Also, it is evident that some sort of matrix by which the thrombin can be prevented from being washed off in the blood stream is needed. Such a supporting substance has been found in fibrin in a form with many spongelike interstices that is called, for convenience, "fibrin foam."⁴ Both thrombin and fibrin foam are but two of the many important results of the work of Cohn and his colleagues⁵ in the Department of Physical Chemistry, Harvard Medical School, under contract between the Office of Scientific Research and Development and Harvard University, to study the fractionation products of human blood plasma. Without doubt the most exacting circumstances demanding hemostasis are those encountered in neurosurgery. In this field the investigations of Bailey and Ingraham⁶ have shown the great value of the fibrin-foam method, in which the foam remains permanently in the tissues but is quite nonirritating and rather quickly absorbed.

The observations presented below, in which the foam method is applied to the prostatic cavity, do not concern the factors of absorption of the matrix. As a matter of fact, the foam has been found to be insoluble in urine.

METHOD

The solution of thrombin is made by dissolving the dry powder in about 10 cc. of an isotonic solu-

*From the Urological Clinic, Peter Bent Brigham Hospital. Presented at the postponed annual meeting of the New England Surgical Society, Boston, February 6, 1946.
†Clinical professor of urology, emeritus, Harvard Medical School; consulting urologist, Peter Bent Brigham and Children's Hospitals.

tion of sodium chloride. In this solution pieces of foam about 1.5 to 2.0 cm square are immersed and agitated until the air in the interstices is largely replaced by fluid. These pieces are then placed in the cavity of the prostate so as to fill it entirely, beginning at its apex and continuing to include the torn edge of the trigone (Fig. 1). Pressure is exerted over

possible, sparking by the high-frequency electric current should be employed. When such a rare arterial spurter is present, it is usually situated just under the torn edge of the trigone in an area readily accessible without removal of any of the foam already in place. Since occlusion of vessels by sparking, even though light, is accompanied by tissue

FIGURE 1

the mass of foam by a thin layer of surgical gauze, and the whole area is subjected to suction through a bent glass tube in the form of the usual perforated douche nozzle. Since the blood is thus drawn into the thrombin-soaked foam, coagulation takes place in about five minutes. Usually no additional hemostatic measure is needed. If a single vessel bleeds so sharply that control by foam and pressure is not

necrosis, this method should be used only when unavoidable.

Patience, continued pressure and suction are the essential factors in the production of hemostasis by this procedure. After complete hemostasis has been obtained the bladder is closed by interrupted sutures of fine catgut. A catheter with a mushroom end (Pezzer), of a size approximately No. 20 Fr., is ad-

sted in the upper angle of the wound for drainage of urine. The structures in front of the bladder are sutured by sutures of fine silk. After operation lavage of the bladder is avoided entirely, indeed, in the absence of bleeding and clot formation such irrigation has no place. The siphon effect of the suprapubic tube is sufficient to carry away the urine soon after it reaches the bladder from the kidneys. A "quiet" bladder, with no stimulus either to expand or to contract, results. This is a significant factor in prompt healing and a smooth early convalescence.

Following operation, fluids are forced to at least 1000 cc daily. The patient is urged to get out of bed on the first postoperative day for a short period in both morning and afternoon. The suprapubic catheter is allowed to remain in place until about the third or fourth day, when the urine is again cleared by the oblique route of insertion, abdominal pressure quickly closes the sinus tract after removal of the catheter, and spontaneous urination is resumed a day or two later. The foam is passed from the bladder in the form of small, slimy bits, without any suggestion of obstruction. If spontaneous urination seems delayed because of the foam, the single gentle passage of either a metal catheter or a sound serves to dislodge the foam. This passage, however, is rarely needed.

RESULTS

In the most recent 88 consecutive cases of prostatic obstruction at the Peter Bent Brigham Hospital, 36 patients were treated by transurethral and 12 by perineal prostatectomy, the suprapubic route was employed in 40 cases, fibrin foam being used as a hemostatic agent.

The age of this last group of patients was as follows: fifty to sixty years, 8 cases; sixty to seventy years, 22 cases; and seventy to eighty years, 10 cases.

The smallest prostate gland weighed 20 gm, and the largest 107 gm, the average being 40 gm.

Preoperative drainage of the bladder was effected through a suprapubic punch in 6 cases and through a urethral catheter (for a short period) in 7, no preoperative drainage was performed in 27 cases.

The urine was clear on inspection two to four days after operation. The suprapubic drain was removed, on the average, slightly over five days after operation. The wound was healed and dry and voluntary urination had been resumed, on the average, eleven and a half days after operation. The reduction in the length of time from operation to resumption of voluntary urination — from fourteen and a half days in the first 10 cases to nine and a half days in the last 20 cases — is to be explained by increased experience regarding the interval after which bladder drainage could safely be abandoned.

Especially noteworthy is the fact that in no case was there any secondary bleeding. Lavage of the bladder was early abandoned, and the distinct impression was obtained that a bladder thus put at

rest, without stimulus to its normal action of expansion and contraction, is an important factor in early healing of the injured area.

SUMMARY

The method employed in the use of fibrin foam as a hemostatic agent after suprapubic prostatectomy is discussed, and the results obtained in 40 consecutive cases are described.

Since the above clinical observations were made, operations have been performed in several additional cases in which bovine thrombin in a matrix of gelatin (Gelfoam) was used instead of the human products. Hemostasis by these materials seemed as satisfactory as that produced by human fibrin and thrombin.

DISCUSSION

DR JOHN M. FALLON (Worcester). I am not competent to discuss Dr. Quinby's paper, but it has been suggested that I talk to you about the use of fibrin foam in general surgery, because these new fractions are, in my opinion, as important in clinical surgery as the older fraction — plasma — to which we are more accustomed.

Human blood fractions, supplied to the clinic through the kindness of Dr. Francis Ingraham by the Department of Physical Chemistry, Harvard Medical School, have been used one hundred and seventy-five times in 160 cases in general surgery. The fractions were thrombin, fibrin foam and Fraction I (fibrinogen), and the purpose of study was the development of applications in general surgery. I shall discuss only the combination of fibrin foam and thrombin that Dr. Quinby has described.

First, so far as the hemostasis of incisions into solid organs is concerned, the most useful application has been in thyroidectomy. Only the larger spurs need be clamped, with six to ten clamps on each lobe. These clamps are tied, and no second round of clamps is applied. The remnant of the thyroid gland is not sutured. Sheets of foam on the cut surface do the rest. The advantage consists not only in reduction of suture material but also in avoidance of trauma to the thyroid remnant. One may intend to leave a fifth or a sixth of the gland, but if such a fifth or sixth is full of sutures it may be physiologically a tenth. The suture that the foam supplants endangers the recurrent nerve crossing behind the gland. Foam has also successfully controlled oozing from incisions into the pancreas, liver and kidney.

Secondly, to obtain hemostasis on soft surfaces and in areolar spaces — spaces on which it is difficult to apply clamps, foam invariably succeeds. An especially rewarding application is to tissues distorted by disease and situated near vulnerable structures like the ureter, phrenic nerve and twelfth nerve, when the foam is substituted for blind clamping and deep sutures. The most frequent application in this group is to the subvesical veins, which are encountered in hysterectomy and in vaginal operations. The neck, the erectile tissues of the labia, the retroperitoneal spaces, the mesentery and the intestine are good examples of such soft areas.

Thirdly, control of direct hemorrhage of large vessels, which was attempted merely to show that it should not be

done, was not tried in human subjects. In eight operations on dogs, major arteries up to 4 mm. in diameter were either opened on the side or transected. With normal blood pressure, the arteries of 2 mm. and sometimes those of 3 mm. were controlled by foam and pressure. Some clots blew off when the blood pressure was artificially raised, but after the blood pressure had returned to normal, new applications of foam invariably held. Two arteries of 4 mm. could not be controlled by foam until the pressure had fallen to dangerous levels.

The use of foam is not recommended for openings into major vessels. In arteries there is the hazard of a large hydraulic pressure acting over a large area, and in veins the added risk of insucked thrombin, causing thrombosis elsewhere in the body. One of my colleagues, however, suddenly faced with a laceration of the vena cava in a patient in bad condition, successfully held a pad of foam over the opening by suturing peritoneum over it. This patient ultimately died from other causes, and autopsy showed neither hemorrhage in the area of the vena cava nor thrombosis elsewhere.

Fourthly, foam is employed as a filler of cavities. Foam is a stuffing that has hemostatic qualities and can be replaced by reparative tissues. Usually only a small amount is needed. Up to 25 cc. has been used, however, without visible ill effect. A dramatic application has been in the removal of Bartholin's cysts. Often the small artery at the upper end of the cyst escapes the clamps, retreats into the spongy paravaginal tissues and bleeds. Foam has ended all this. Wens, stripped varices and ganglions—that is, areas that can later be watched from the surface—when filled with foam have done well. And deeper, larger areas that cannot be watched, like the pararectal space, seem to have done well.

Fifthly, foam is used as a dressing. Following an accidental observation that better epithelium seemed to grow more quickly under foam, such dressings were used on several skin

defects and in two defects of the mucosa (mouth and es-moid), with good results. Foam, incidentally, is an excellent dressing for anal operations. At the end of an operation the anoscope can be reinserted to check what has been done without fear of stirring up hemorrhage if followed by a foam plug. Foam has also been used as an internal dressing, wrapped around intestinal anastomoses in dogs and in human beings, but it is not yet possible to report the results.

Complications include the danger of squeezing thrombus into a large vein. Two out of 160 patients had femoral thrombosis. This incidence is high, but the total group is small for conclusions. However unscientific it sounds, this was a group of patients picked from a larger total and containing most of those members of the total who were likely to have thrombosis.

Finally, blood fractions are neither an excuse for carelessness nor a substitute for good judgment, but the knowledge that blood fractions were available led me to attempt procedures that a few months previously would not have been considered. Amusingly, the fact that the foam was available has increased my respect for simple pressure. Often, by the time the foam reached the table, the bleeding had stopped, when foam was added, however, there was no fear that hemorrhage would occur.

DR. FRANC D. INGRAHAM (Boston): There is nothing for me to add to Doctor Quinby's paper or to Doctor Fallon's discussion. My experience has been chiefly with the use of the materials described in neurosurgical patients.

I should like to emphasize the facts that during the war all these materials were derived from Red Cross blood and that none of them were distributed to civilians except as testers for the armed forces. After the material had been released by the testing group, it was sent to the Army or the Navy.

TREATMENT OF MENTAL ILLNESS AT HOME BY SMALL DOSES OF INSULIN

An Appraisal of Results in Twelve Cases

NEWMAN COHEN, M.D.*

BOSTON

SINCE the introduction of insulin coma in the treatment of certain mental disorders by Manfred Sakel in 1933, the method has gained wide acceptance. The most extensive evaluation of the results with insulin coma is contained in a recent report of the New York Temporary Commission on State Hospital Problems,¹ which strongly favors insulin as being of definite value in the treatment of schizophrenia. This report is based on 1128 patients treated with insulin and on 876 control patients who did not receive any form of shock treatment. The former group had a definitely shorter period of hospitalization than the latter, as well as a longer period of satisfactory adjustment at home and a higher level of usefulness in the community. This type of therapy is drastic, however, and requires hospitalization, and there are a large group of patients whose mental condition does not require hospitalization. The purpose of this paper is to present experiences with a modified form of insulin-coma therapy in such patients at home.

The possibilities of insulin subcoma as a method of therapy have been only scantily explored. The

first report of the therapeutic use of mild hypoglycemic shock was that of Cowie et al.,² who in 1923 noted that depressed states frequently cleared up during the insulin treatment of diabetes.

Subsequently, other reports suggested that such therapy might be beneficial. Among these is the work of Targowla and Lamache,³ who in 1926 used insulin on 2 undernourished, depressed psychotic patients, and of Miskolczy,⁴ who in 1927 worked with insulin in a variety of neurologic conditions.

In 1929 Appel and his associates⁵ found insulin subcoma of value in improving the appetite and the nutritional and mental status of patients suffering from neurasthenia, depressive states and dementia praecox. The amount of food intake was increased in practically all cases, and the gastrointestinal function seemed to be improved. The dry, gray, flabby skin soon took on a healthy appearance. Not a few patients gained weight to an extent not previously experienced—a remarkable observation, since most of the patients were over forty-five years of age.

The first report on the prolonged therapeutic use of repeated mild hypoglycemic shocks over a long period in mental disorders was that of Polatin, Spotnitz and Wiesel⁶ in 1940. Their group included

*Assistant, Boston State Hospital and Southard Clinic, Boston Psychopathic Hospital.

3 patients with schizophrenia, manic-depressive psychosis and psychoneurosis and 4 with psychoses due to brain damage. The treatment consisted of daily hypodermic injections of small doses of insulin — initially 5 units, increased by 5 units daily to the point of mild hypoglycemia. The hypoglycemic symptoms usually began to manifest themselves about two hours after injection and gradually increased in severity. Patients remained in this state for from fifteen to forty-five minutes, depending on the degree of the hypoglycemia, which usually terminated with breakfast three or four hours after injection. During the hypoglycemia, the patients were up and about and were able to feed themselves at breakfast without assistance. They were treated daily for an indefinite period until improvement occurred. This ranged from one week to eighteen months. It was noted that most patients gained weight and that all became easier nursing and feeding problems. Of the 22 patients treated, 1 recovered, 12 were improved, 5 were slightly improved and 4 remained unimproved. No coma, allergic manifestations, convulsions or injuries occurred. These studies indicate that mild hypoglycemic shock is of considerable value in the treatment of mental disorders. The authors emphasize the fact that beneficial effects were slowly accumulative and that prolonged treatment was necessary before satisfactory results were observed. Subsequent reports of these authors^{7, 8} in a large series of cases have confirmed their original impressions.

In 1940 Bennett and Miller⁹ tried subshock doses of insulin in psychotic patients presenting difficulties in management. The treatment was given in 125 cases presenting extreme nursing problems, and in nearly every case of acute manic excitement was controlled without sedatives within an average period of thirty-six hours after adequate insulin dosage. The use of sedatives was practically eliminated in cases of extreme psychomotor activity.

Ambulatory insulin therapy was utilized by Tomlinson and Ozarin¹⁰ in 1942, according to the method described by Polatin and his co-workers. In a group of 52 unselected cases, 34 patients (65 per cent) improved, 5 (10 per cent) improved and then relapsed and 13 (25 per cent) showed no improvement. A year after this program had been initiated, 13 patients (25 per cent) had been paroled from the hospital. In dementia praecox, paranoid type, which comprised the largest number of cases treated, 60 per cent of patients were definitely improved. It is interesting that a patient with Alzheimer's disease improved and that 2 parietic patients showed a favorable response.

Rennie,¹¹ in 1943, reported 28 heterogeneous cases in which insulin in doses of 50 to 90 units daily over a period of twenty to fifty days gave especially gratifying results in the relief of excitement, overactivity, inner tension and, particularly, anxiety. Rennie found that insulin sedation was superior to

sedation by ordinary chemical methods, the effects being more incisive and lasting. It was apparent that dramatic relief could be achieved with insulin in various kinds of excitement whenever anxiety prevailed. Insulin therapy permitted a marked degree of relaxation, released ability to discuss pre-occupations easily and provided the therapist with a real opportunity to understand the patient and his basic needs.

Beneficial results with subcoma insulin have been reported in the treatment of acute alcoholism¹² and the relief of severe migrainous headaches¹³ and as an aid in rehabilitating soldiers suffering from acute panic, protracted states of anxiety and chronic weight loss.^{14, 15}

A recent report by Sands,⁶ summarizing his experiences in 163 cases, advocated subcoma insulin in the treatment of war neuroses.

Referring to insulin subcoma treatment of ambulatory patients, Brickner¹⁷ states that the method is extremely useful in the relief of tension associated with practically every type of mental or emotional disturbance.

The following report deals with the results of prolonged subcoma insulin treatment in a consecutive series of 12 ambulatory patients with chronic mental illness that had been refractory to other forms of management.

METHOD

Breakfast is withheld each morning. Insulin injections are given six times a week in increasing amounts until mild hypoglycemic shock, manifested by weakness, copious perspiration, hunger and drowsiness, is produced. Usually 50 to 90 units is a sufficient dosage. When mild hypoglycemic shock occurs, the dosage is maintained at the same level so long as the optimum effect continues. In some cases, however, the dosage must be further increased.

Mild coma occasionally supervenes, but the patient is deliberately prevented from going into deep coma. Generally it is observed that after several weeks of continued insulin therapy, the patient develops a certain amount of sensitivity to insulin, and thereafter it is possible to obtain reactions with a reduced dosage. The insulin dosage is at all times kept at a minimal level, and the intensity of the hypoglycemia is controlled by feeding. In this way, patients feel more comfortable, whereas with larger doses they are apt to express feelings of discomfort and even to suffer from nausea and other gastrointestinal manifestations.

As a rule the hypoglycemic manifestations appear in approximately an hour. If insulin is injected intravenously the symptoms usually appear in an appreciably shorter period. Generally the patient is quite comfortable during the first half hour, although there are individual variations.

Experience shows that frequent modifications and variations are often essential for the success of this

method During the treatment patients are up and about, but, if they prefer to lie down when the hypoglycemic manifestations become upsetting, they are permitted to do so

It is advisable that the patient be kept under constant observation by the physician or a trained nurse, and that the pulse, blood pressure, respiration and general clinical status be checked at frequent intervals Those in attendance are instructed regarding the complications that may arise and their management Barbiturates are contraindicated during the insulin series, since they may negate the effect of the insulin

The patient is permitted to remain in a state of mild hypoglycemic shock for a variable length of time, and termination is then brought about as described above In the early phases of hypoglycemia, psychotherapeutic discussions are carried out

The results of the method of therapy in the following 12 cases appear to justify its continued use

CASE 1 A 28-year-old married Italian immigrant who had suffered considerable early privation in his native land came to America at the age of 17 and successfully operated a barber shop until November, 1943, when in response to wartime stress he developed marked tension, restlessness, anxiety and obsessive fears, the most prominent among which was worry that he would slit the throat of his customers while shaving them This led to a marked inefficiency and almost complete incapacity in his work He complained of weakness, pain, dizziness, insomnia, anorexia, tremors and temper outbursts

Insulin subshock was begun on January 28, 1945 Improvement was first noted on February 26, and thereafter there was a gradual abatement of all symptoms until complete recovery on May 13

The patient was entirely well at follow-up examination 8 months later

CASE 2 A 30-year-old married Italian woman with a history of attacks of depression at the ages of 16 and 26, succumbed to a third depressive psychosis in March, 1944, following her husband's entry into the armed forces

The symptoms consisted of insomnia, numerous somatic complaints, worry, fatigue, spells of weeping and obsessive longing for her husband The illness continued for a year, and the patient lost a total of 39 pounds in weight

She made a suicidal attempt by swallowing iodine Neither hospitalization nor electric shock treatments were permitted The constant threat of suicide made the situation desperate

On March 17, 1945, insulin subcoma treatment was begun, and the patient made a dramatic improvement in 5 weeks In 12 weeks she had regained 23 pounds in weight. She was cheerful, interested, self-reliant and confident about the future Recovery persisted

CASE 3 A 40-year-old married woman, whose family history revealed suicide of one parent and whose early life had been essentially normal, first developed symptoms in 1941 following an attack of influenza She showed the typical reactions of a shut-in personality Tension, nervousness and obsessive fears persisted for months, resulting in marked incapacity There was a sense of impending disaster, as well as various somatic complaints Extreme emotional instability — characterized by laughing and crying spells, agitation and panic reactions — resulted in a state of utter helplessness This condition remained unabated except for short periods of relief during the summer months

Prolonged treatment with barbiturates and other drugs was unsuccessful Orthodox psychotherapy by several competent psychiatrists, as well as several years of psychoanalysis, was of no avail in alleviating the symptoms Electric-shock therapy was equally unsuccessful, except for a brief period of partial relief of symptoms An exhaustive medical examination failed to reveal any evidence of organic disease

In May, 1945, insulin therapy was initiated, beginning with a dose of 10 units and increasing the dosage daily until symptoms of mild hypoglycemic shock were present Sixty treatments in all were given, the maximum dose being 90 units

After 5 weeks of treatment, there was a gradual and remarkable remission of the symptoms Tension and anxiety diminished, the weight increased steadily and the patient was able to resume social activities and derived considerable pleasure and satisfaction out of life She became more accessible to psychotherapy, and improvement continued steadily until complete recovery 10 weeks after the initiation of the therapy

The patient subsequently remained well, and for the first time in 5 years was not confined to bed during the winter

CASE 4 A 56-year-old married man with a noncontributory family history had suffered for 6 years from pain in the post-thoracic region radiating laterally A diagnosis could not be established despite the concerted efforts of many specialists Novocain nerve-root injections were given, but after 3 weeks of comparative comfort the pain returned

The patient suffered for 8 months, during which x-ray treatment of the spine gave temporary relief Exercises and diathermy given by an osteopath aggravated the pain Opium gave partial amelioration during hospitalization After a second novocain injection the patient collapsed completely and had to remain in bed for several days

A depression followed The symptoms consisted of despondency, loss of weight and poor appetite No response was obtained to sedatives

At a private sanatorium a course of electric shock treatments brought some palliation for 9 months, but in February, 1945, the patient relapsed into depression Various forms of medical management proved ineffective The patient had crying spells and suffered from anhedonia, insomnia, inability to concentrate, a host of bodily symptoms and extreme anxiety

Insulin subshock treatment was begun on May 11 The response was most encouraging, the patient began to gain weight, the appetite improved and he was able to work and showed renewed and sustained interest He was treated until August 27, when he felt well enough to take a vacation for a week Improvement lasted until October 9, when the patient reacted to slight external stress by becoming mildly depressed

He continued to receive additional treatment intermittently, during which his condition fluctuated For an occasional day or so he slept poorly and complained of headaches and vague pains In general, however, his condition remained satisfactory He was able to attend to his business duties, which he had not been able to do satisfactorily before treatment The depression largely abated, and the patient gained weight and appeared well

CASE 5 A 37-year-old, overprotected, married Italian woman, with a history of nervousness in childhood and difficulty in adjustment in play life, first succumbed to a clearly defined illness in the post-partum period of her first delivery She developed weakness, apathy, loneliness and seclusiveness Two years previously, following the death of her mother, she had been depressed for 4 months

In June, 1945, she suffered an acute turmoil reaction characterized by irritability, mood swings, agitation, delusions and hallucinations No effect was obtained by a variety of medication or by a change of environment

Insulin subshock treatment was immediately begun, and in 2 weeks the symptoms began to clear A total of 92 subshock treatments were necessary to restore the patient to mental health

She was well when last seen

CASE 6 A 26-year-old married man had been insecure, inadequate, emotionally unstable, suspicious and distrustful since the loss of his parents at an early age He constantly complained of somatic disease, lack of energy and fatigue and indulged in self-reproach His mood was chronically depressed

Insulin subshock treatment was begun on June 30, 1945, and in a month the patient was able to handle his anxiety more adequately His emotional life reached an even keel and his outbursts became infrequent Treatment was continued with some interruptions until September 15 The pa-

ent was considerably improved but not completely relaxed further treatment was omitted, however

The patient was mentally recovered at follow-up examination 6 months later

CASE 7 A 42-year-old spinster became seriously ill in 1931 following a clandestine affair with a married man interested only in exploiting her. Suffering from anorexia and vomiting, he gave up her job and retired to a life of invalidism. She radically sank into a state of tiredness, lassitude, self-depreciation, seclusiveness and emotional instability. Regurgitation and vomiting followed any suggestion of social intercourse.

Despite numerous attempts at medical management and psychotherapy, the condition continued unabated for 14 years—the only significant change being that the patient became more depressed and despondent. Since the family refused permission for electric-shock treatment and frowned on hospitalization, insulin subcoma treatment at home was begun on July 18, 1945, and continued for 4½ months.

The first short period of improvement was noted in 6 weeks thereafter, intervals of well-being became more prolonged. Psychotherapeutic sessions were soon possible with a patient who had previously been inaccessible. Hope and confidence came into the life of a woman who had been mentally ill for 14 years. The patient returned to work, and social adjustment was excellent.

CASE 8 A 40-year-old married woman, whose mother had been neurotic and whose father had been alcoholic, had led a gay, cheerful and useful life until a cesarean section in 1942 resulted in a dead infant. Both the patient and her husband were deeply grieved over the loss, with intensification of dissatisfaction and yearning when future months left them barren and childless. The patient began to blame herself and expressed feelings of guilt over past sexual indiscretions and excessive concern over a brother's neuropathic tendencies. This condition continued intermittently until 1943, when she became seriously depressed and was treated with electric shock, which gave only temporary relief.

In June, 1945, the patient presented a picture of anxiety, somatic disturbances, marked phobias and a fear of death oscillating with periods of gaiety and euphoria. Insulin subcoma treatment was begun in August, and continued for 4 months, the patient receiving a total of ninety-six treatments. Ten weeks of treatment resulted in loss of anxiety and of feelings of guilt. She gradually became more objective, contented, active and stable in her adjustment to her environment.

Follow-up study 4 months later revealed that the patient had not lost any of the gains made under insulin subcoma treatment.

CASE 9 A 46-year-old, married, artistic woman, overwhelmed by the shock of several deaths in her family and a serious heart ailment in her husband, succumbed in 1944 to an illness marked by fatigue, anxiety, gastric distress and abhorrence for food and water. Financial difficulties, more bereavements and an increasing feeling of loneliness seemed insuperable obstacles to recovery. Of psychological interest was the fact that on several occasions news of a death in the family came at the time the patient was eating a meal, avoidance of food and drink was the result of this conditioning. Amenorrhea of 6 months' duration developed, the patient took to barbiturates, with indulgence to levels of mild toxicity.

Insulin subshock treatment was begun on August 21, 1945. Improvement was noted in 1 month, the patient slept well without medication and actually experienced pleasurable sensations of hunger and thirst without distress at their satisfaction. At the end of fifty treatments she had gained 12 pounds in weight. Curiously, she showed little enthusiasm for her recovery and weight gain and a reluctance to continue with the therapy, which was soon discontinued.

Follow-up after 5 months revealed that patient had slipped slightly and returned to her former weight level, but as she was no longer a barbiturate addict, she could engage with interest and enjoyment in art, and seems to have partially maintained her improvement.

CASE 10 A 47-year-old married man became ill in 1942, when he suspected his wife of a clandestine love affair. The symptoms consisted of insomnia, worry, crying spells, in-

ability to concentrate, loss of interest and spontaneity. He hired detectives to trail his wife and contemplated divorce. In May, 1944, he had an attack of coronary thrombosis. This preyed on his mind and added to the already heavy strain. He constantly chided his wife for his mental state and cardiac disease. During a vacation trip to Florida he was unable to eat or sleep and paced the floor at night, repeatedly accusing his wife, with resulting tension, discord, unrest and bitterness. The distress was not relieved by barbiturates, health resorts, osteopathic treatments and therapy from competent internists and psychiatrists.

Insulin subshock treatment was begun in October, 1945, after assurance by medical specialists that the patient was a good risk. On November 19, a definite upturn was noted. He lost considerable anxiety and gradually became more amenable to psychotherapy. He was able to see his mental problem in a new light.

The remission lasted until February, 1946, when the patient was again beset by doubts, fears and obsessions, which were of short duration, however. As treatment was continued his anxiety completely disappeared, he became jovial and interested in life and resumed the operation of a large and successful business. A total of one hundred and two subshock treatments completed the series.

The excellent home and business adjustment continued.

CASE 11 Following a series of abdominal operations and a loss of 30 pounds in weight, a 38-year-old married woman, whose personality was characterized by egocentricity, selfishness and excessive self-esteem, became embarrassed and self-conscious, lacked interest, ambition and spontaneity and showed excessive irritability when crossed. She complained of fatigue and headaches. The patient took refuge in barbiturates and suffered from mild barbiturate addiction.

Insulin subcoma treatment was begun in November, 1945, and definite improvement was experienced starting with the eighth treatment. Progressively there was a return of appetite and sense of well-being and a gain of 12 pounds in weight. The patient was more relaxed and showed no anxiety or irritability.

After the forty-sixth treatment insulin subcoma was omitted because of a death in the family. Thereafter the patient refused to co-operate for further treatment, stating that the therapy was too restraining and interfered with her social life.

Loss of weight, insomnia, return of irritability and barbiturate addiction followed the cessation of treatment.

CASE 12 The whole life pattern of a 23-year-old man had been characterized by marked inadequacy, self-consciousness, immaturity, lack of drive, initiative or sustained interest, and excessive sensitivity to criticism and rebuke. He broke down in 1939 following the loss of a Government job and consequent severe disappointment in his future. He became more dependent and resentful of others and displayed outbursts of temper. In 1945, examination revealed an introverted, weak-looking man, who was lacking in confidence and complained of poor appetite and insomnia. He had been socially maladjusted, with low spirits, had had frequent crying spells and had not evinced the slightest interest in girls.

Following one interview, conducted under sodium amytal, insulin subcoma treatment was begun in December, 1945. A slight improvement was noted 5 weeks later. The patient gained 10 pounds but was still shaky, unstable and resentful toward his parents. Improvement with further treatment was steadily progressive. Ten weeks after treatment was begun the patient was eating and sleeping well and had gained confidence and poise, and his spirits had risen.

Insulin subcoma treatment has proved valuable in a variety of mental conditions and in many cases that have been refractory to other methods of management.

This treatment has the following advantages: it can be administered in the patient's home and thus obviates the stigma (in the minds of the patient and his relatives) of hospitalization—none of the current drastic methods (electric-shock treatment, insulin-shock treatment and lobotomy)

can be applied readily at home, the method is relatively safe when administered by well trained personnel who are in constant attendance during the period of treatment, the aftercare is rather simple and imposes no undue hardship on either the patient or those in attendance, insulin subcoma is less drastic than actual shock treatment and in all probability produces no irreversible brain damage (patients given as many as one hundred and two subcoma treatments showed no evidence of mental deterioration), the treatment, which is not incapacitating and during which the patient is more or less conscious and usually able to be up and about, has two important advantages over other methods — first, the patient can participate in the psychotherapy, can speak freely of his preoccupations and experiences and can better unburden himself of his distressing thoughts, enabling the therapist to obtain a closer understanding of the patient and his basic needs, and secondly, at the termination of the treatment, the patient is alert and able to join in activities immediately and is not in the toxic, beclouded state characteristic of electric-shock treatment, insulin-coma treatment or heavy barbiturate medication, insulin subcoma greatly relieves basic anxiety — according to Rennie¹¹ the improvement appears to run parallel with the disappearance of dynamic anxiety, although the period of treatment is more prolonged than that in the more drastic types of therapy, the beneficial effects are usually quickly apparent and cumulative, and finally, the effects of subcoma insulin treatment are more incisive and lasting than those with chemical sedation,¹² which often increases anxiety rather than relieving it.

Chemical methods (interviews conducted under sodium amytal) are apt to be rejected by the patient as an aggressive attempt to elicit painful memories that he would prefer to remain hidden.

The period of follow-up study in the cases reported above varied between four and nine months. The final evaluation of this method of therapy must await a longer study of all these cases, as well as a careful investigation of a larger series of cases. The results, however, even in the short period of observation, were quite encouraging and support the findings of Rennie, Brickner, Polatin and others.

Subcoma insulin treatment seems to have almost a specific effect in relieving anxiety and tension. The role that anxiety and tension plays in misinterpretations, delusions and depressions can hardly be overestimated.

A natural disadvantage of this type of treatment in the patient's home is the time factor, several hours of the physician's attention usually being re-

quired. With this precaution, the treatment is relatively safe. It is emphasized that insulin subshock treatment must not be given promiscuously and haphazardly.

SUMMARY

Subcoma (mild hypoglycemic) shock therapy can be administered at home to ambulatory patients with comparative safety. Twelve cases are reported, with results that appear to justify further use of the treatment. The method of administration and the necessary precautions to safeguard the patient are described.

The advantages of repeated subcoma insulin shock treatment are enumerated. Weight gain and increased sense of well-being are important concomitants.

Patients with varying neuropsychiatric conditions, some of which were refractory to other methods of management, showed dramatic improvement or recovery. The beclouded, toxic state regularly encountered with the more drastic types of therapy, such as electric shock and insulin coma, is largely eliminated.

In view of the favorable results encountered and the hopeful reports in the literature, further use of this method is believed to be warranted.

THE SIGNIFICANCE OF MEDIASTINAL EMPHYSEMA*

A Report of Two Cases

W P VANDERLAAN, M D,† AND GEORGE MARESH, M D ‡

BOSTON

SPONTANEOUS mediastinal emphysema is now a well recognized clinical entity to which considerable attention has been called. Although Jamman¹ enumerated several routes by which air reaches the mediastinum, the finding of extensive mediastinal and subcutaneous emphysema may at times be too readily attributed to this relatively benign disorder and a serious underlying disease overlooked. It is the purpose of this paper to call attention to that possibility by presenting 2 cases. In Case 1 spontaneous mediastinal emphysema occurred twice, and at the time of recurrence mediastinal decompression became necessary. In Case 2 extensive mediastinal and subcutaneous emphysema was dependent on a serious underlying disorder, discovered at autopsy to be spontaneous rupture of the esophagus. Some points of similarity and the differential diagnosis of the two conditions are discussed below.

CASE 1 I B, a 19-year-old girl, entered the hospital because of severe substernal pain and dyspnea. She had been well until 3 days before entry, when she had noted a head cold. Eight hours before admission she suddenly began to cough and vomited. She felt ill and went to bed, where 15 minutes later she experienced a sudden violent pain over the xiphoid process radiating through to the back but not to the shoulders or arms. The pain was accompanied by severe dyspnea and orthopnea and was aggravated by coughing, by deep breathing, and by lying on the right side. The pain continued undiminished until the time of entry.

Physical examination revealed a well developed, well nourished girl who appeared to be acutely ill and in respiratory distress and who was breathing shallowly and regularly. The temperature was 100.2°F, the pulse 108, and the respirations 30. The blood pressure was 130/95, falling to 110/70 about 4 hours later. Creptus was felt over the face, the occiput, the entire neck and the upper anterior chest. The trachea was deviated slightly to the right. The left side of the chest was hyperresonant, with diminished breath sounds. The area of cardiac dullness was obliterated. The heart sounds were distant, no abnormal sounds were heard. Percussion over the liver revealed dullness. There was no cyanosis or venous engorgement. The remainder of the examination was not remarkable.

The urine was normal. Examination of the blood revealed a hemoglobin content of 80 per cent, and a white-cell count of 14,000, which fell to 6350 on the 2nd hospital day. A blood Hinton test was negative, and a blood culture yielded no growth. A chest roentgenogram, showing a fine line of decreased density to the left of the sternal border that extended down the sternal border and about the pericardium, was regarded as consistent with mediastinal emphysema; there was no pneumothorax. An electrocardiogram was within normal limits.

The patient was placed in bed and given intranasal oxygen, a tight chest binder, codeine and aspirin and sulfamerazine.

*From the Thorndike Memorial Laboratory, the Second and Fourth Medical Services (Harvard) Boston City Hospital and the Department of Medicine, Harvard Medical School.

†Junior assistant physician Joseph H. Pratt Diagnostic Hospital, research assistant, Tufts College Medical School, formerly assistant in medicine Harvard Medical School and Boston City Hospital.

‡Formerly resident physician Boston City Hospital.

She was fairly comfortable, showing gradual symptomatic and objective improvement, but continuing to run a slight temperature. On the 2nd hospital day muffled crackling or crunching sounds synchronous with systole were heard over the apex of the heart, disappearing within a few hours.

On the 4th hospital day, while the patient was lying quietly in bed and not coughing, she had a sudden recurrence of severe pain and shortly became cyanotic, dyspneic and irrational. Bilateral subconjunctival hemorrhages appeared. Morphine did not control the pain, and oxygen administered with the aid of a Boothby mask gave no relief. The respirations rose to 40, the pulse to 140, and the blood pressure to 160/120. Creptus reappeared over the face, but auscultation of the heart and lungs revealed no abnormality.

The patient was transferred to the operating room, where a 7.6 cm., low-collar incision just above the sternal notch was made under local anesthesia. The muscles were separated in the midline, and a finger was inserted into the superior mediastinum through the suprasternal notch. There was an egress of air, and rapid improvement in the status of the patient followed. The subcutaneous emphysema disappeared gradually, and convalescence was uneventful.

CASE 2 C M, a 58-year-old married man, entered the hospital complaining of abdominal and chest pain of 6 hours' duration. He had consumed considerable quantities of alcohol daily for many years, but he had remained well until 6 hours before hospital admission, when, shortly after carrying a heavy load of brass, he suddenly vomited copious amounts of brown liquid material, there had been no previous nausea. He continued to retch for 5 minutes. He noted marked weakness and shortness of breath, and experienced a severe pain in the anterior and posterior chest and in the upper abdomen, the pain was made worse by deep breathing. After going to bed the patient felt less dyspneic but observed that he was hoarse. Thereafter he noted that his neck was swollen. He had two more episodes of vomiting before entry. He had never had jaundice, ascites or ankle edema. The appetite had been poor, but there had been no dysphagia. No other contributory information was elicited.

On physical examination the patient was obese, flushed and in respiratory distress. The temperature was 101°F, the pulse 104, and the respirations 32. The blood pressure was 110/66. On palpation there was creptus over the mandible, the entire neck and the anterior chest to the costal margin. The trachea was in the midline. There were prominent superficial veins over the right anterior chest. The anteroposterior diameter of the chest was increased. Tactile fremitus and resonance were decreased over the left lower lobe, and the breath sounds were faint. No rales were heard. The remainder of the chest was hyperresonant. The area of cardiac dullness was obliterated, but this finding was difficult to evaluate because of the emphysematous chest. The heart sounds were faint, and no murmurs were heard. Except for slight upper abdominal tenderness, there were no noteworthy physical findings.

No abnormality of the urine was noted. Examination of the blood revealed a hemoglobin of 80 per cent and a white-cell count of 3450, which rose to 15,200 on the 2nd hospital day. Examination of the sputum revealed no tubercle bacilli. The vomitus and a stool were guaiac negative. The blood Hinton reaction was equivocal. The venous pressure in the antecubital fossa was equivalent to 150 cm. of water, and the arm-to-lung circulation time, which was tested with paraldehyde, was 15 seconds. Roentgenograms of the chest and of the neck were regarded as consistent with mediastinal and subcutaneous emphysema. An abdominal film was within normal limits. An electrocardiogram showed sinus tachycardia, with slightly low origins of the ST segments in Leads 2 and 4.

On bed rest the temperature quickly returned to normal and the dyspnea disappeared. In the hope of hastening resorption of air from the mediastinum, oxygen therapy was instituted.

About 14 hours after entry the patient again became dyspneic and the blood pressure fell to 80/40, where it remained until shortly before death. On the 2nd hospital day crepitant rales were heard at the lung bases. Because of the rales and the elevated white-cell count, although the temperature was normal, sulfapyrazine was given in full doses orally. A roentgenogram of the chest was interpreted as showing atelectasis of the right and left lower lobes. Later in the day the patient became violent, tearing away his oxygen mask repeatedly. The pulse rose to 130 and was of small amplitude. Dyspnea followed by cyanosis ensued, and since the signs of mediastinal emphysema were still marked it was believed that the only therapeutic measure with a reasonable chance of success was mediastinal decompression.

The patient was removed to the operating room where the superior mediastinum was entered digitally after a low collar incision had been made. There was some egress of air, cultures of the mediastinum were made, and the wound was closed about a rubber dam. For about an hour the patient appeared to breathe more easily and to be making slight improvement. Despite supportive measures, however, he slowly weakened and died 9 hours after operation and 48 hours after the onset of symptoms.

Autopsy. At post-mortem examination subcutaneous and mediastinal emphysema was found as clinically described. The essential abnormality was a longitudinal linear rupture of the esophagus, 2 cm long, just above the esophageal hiatus of the diaphragm. It communicated with a cavity containing foul, dark-brown fluid, which bulged against the posterior aspect of the pericardium and was walled off from the left pleural cavity by fibrinous adhesions. Microscopically there was no evidence of peptic ulceration of the esophagus. Gas-forming bacilli were not found in the swabs taken from the chest at operation or at autopsy, although suitable procedures for culture were carried out. Additional findings were bilateral pleuritis due to a Type 5 pneumococcus, congestion and edema of the lungs, with bronchopneumonia, and moderate alcoholic cirrhosis of the liver. Death was attributed to respiratory embarrassment.

The pathogenesis, pathological physiology, clinical manifestations, diagnosis and treatment of mediastinal emphysema have recently been reviewed by Hamman,⁴ who indicates the need for mediastinal decompression when signs of high pressure within the mediastinum manifest themselves, although in the absence of these signs rest and symptomatic measures suffice. Hamman lists four possible routes along which air may reach the mediastinum through the fascial planes of the neck, through a perforation of the trachea, bronchus or esophagus, from the retroperitoneal space, and from the interstitial tissues of the lung. The entrance of air into the mediastinum via the second route rarely occurs, but Hamman further states:

No doubt at times air may enter the mediastinum through a perforation of the esophagus. However, where this accident occurs there is always infection and the serious symptoms of infection obscure the lesser symptoms that may arise from a small amount of air entering the mediastinum.

This statement seems somewhat at variance with the findings in Case 2, indeed, McWeeny² described emphysema as one of the most striking and constant findings in spontaneous rupture of the esophagus. Ridgway and Duncan,³ in a review of the literature, found emphysema present in a half to two thirds of the cases.

Case 1 provides an example of uncomplicated mediastinal emphysema, although it may be questioned whether it should be classified as an example of spontaneous mediastinal emphysema (Hamman's syndrome) or whether it should be excluded from the spontaneous type on the basis that fifteen minutes or more prior to the onset of pain the patient had experienced increased intrathoracic pressure associated with coughing and vomiting. The recurrence was known to have happened without any unusual exertion while the patient was in bed in the hospital. Thus it was clearly spontaneous. Regardless of classification this case illustrates the dramatic improvement that occurs with decompression of the mediastinum when the tension within the mediastinum is so great as to embarrass the circulation.

Case 2, which to those in attendance simulated Case 1, was nonetheless clearly one of spontaneous rupture of the esophagus. The findings were typical of the classic descriptions of the condition,^{2,4} the patient being a man, in middle life and alcoholic. Vomiting and retching immediately preceded the illness, which was characterized by a sudden onset, pain in the lower chest and upper abdomen, and shock, with dyspnea and subcutaneous emphysema. Spontaneous mediastinal emphysema, however, occurs in both sexes, alcoholism is not a factor and the condition arises without apparent precipitating factors. In spontaneous rupture of the esophagus—the term "spontaneous" being used rather loosely, but serving to exclude external trauma—violent retching and vomiting, often following the ingestion of an extraordinarily large meal, usually precede the attack. Both emphysema and esophageal rupture have a sudden onset, pain in the former being restricted to the chest, but in the latter, upper abdominal pain, sometimes with a boardlike abdomen, is found in addition to the chest pain. The pain in both syndromes may be aggravated by breathing, but marked thirst and shock are suggestive of esophageal rupture. The extent of emphysema is not of aid in the differential diagnosis, in fact, after esophageal rupture, it has been observed to involve the whole body. Aspiration of the chest through a needle may clinch the diagnosis by revealing the presence of gastric juice or food particles.

The course of spontaneous mediastinal emphysema is usually benign, but, as Hamman states, prompt decompression of the mediastinum may prove life-saving if the venous return to the heart becomes seriously impeded. In contrast, early intervention in spontaneous rupture of the esophagus seems mandatory, although closed drainage of the pleural cavity,⁴ with chemotherapy, may be the procedure of choice.

A few additional points regarding spontaneous rupture of the esophagus may be of interest. This syndrome appears to bear a considerable relation to that described by Mallory and Weiss,^{5,6} in which

NEW HAMPSHIRE MEDICAL SOCIETY

Proceedings of the One Hundred and Fifty-Fifth Anniversary

THE scientific session of the New Hampshire Medical Society convened at 9 30 o'clock on the morning of May 14, 1946, with President Richard W Robinson, of Laconia, presiding

The first item on the program was a motion-picture film entitled "Angina Pectoris," presented through the courtesy of Brewer and Company, Incorporated. The President introduced Dr Paul C Barton, medical director of Brewer and Company, who before the war was director of the Bureau of Investigation of the American Medical Association and during the war served as executive officer of the Procurement and Assignment Service. Dr Barton presented the motion picture. A paper "Autopsy Service — Mary Hitchcock Hospital" was then presented by Dr Ralph E Miller, of Hanover. This was followed by a paper by Dr Edwin B Astwood, of Boston, Massachusetts, entitled "Present Status of the Medical Treatment of Thyrotoxicosis." Dr Louis H Bauer, a trustee of the American Medical Association, then presented a paper "The Medical-Care Problem in the United States." The morning session was concluded at 1:00 p m.

The afternoon session opened with the awarding of fifty-year certificates to Dr H Sheridan Baketel, of Greenland, and Dr Oscar C Young, of Charlestown. Dr Baketel, on receipt of his certificate, spoke as follows:

The presentation of this certificate, commemorating my continuous membership in the New Hampshire Medical Society for fifty years, is fraught with especial significance.

To some men, it might merely mean that they had been in the Society for half a century, exactly as if they had voted the same national ticket for a similar period or carried the same watch. To me, this occasion reaches deeply into my inner consciousness. When I was a small boy in Greenland, riding with my medical idol and inspiration, the late Dr William Oliver Junkins, of Portsmouth, I learned that in taking on the great responsibilities of medical practice, the physician is duty bound to make himself a living part of his profession. This fact was accentuated in my mind while in Dartmouth. The two men who then had such a major part in shaping the minds and ideals of medical students, Drs Carlton P Frost and William T Smith, impressed us with the necessity of allying ourselves with the Society at the earliest opportunity — advice that I followed.

Next to the award of my medical degree in 1895, my proudest moment was the day I received from the secretary of the New Hampshire Medical Society, and one of my most respected Dartmouth professors, the late Dr Granville P Conn, the certificate of membership, dated June 7, 1896. That parchment is one of my most treasured possessions today.

I belong to fifteen or more medical associations and am proud to be a life fellow of the American College of Physicians, but the pleasure of election to these professional groups was never accompanied by the thrill that coursed through my body on that memorable June 7.

Destiny decreed that the past forty-four years should be spent in New York City or adjoining New Jersey, and although I was active there as a practitioner, medical-school professor, editor and research worker, my spiritual self was ever in the Granite State.

My beloved father, the late Rev Dr Oliver S Baketel, brought his family from our native Ohio to Newfields in 1877, and there at the age of four my interest in the State was aroused. It was enhanced at Portsmouth High School, Phillips Exeter Academy and Dartmouth College, where we were taught to venerate the Granite State.

New Hampshire became almost an obsession. I have always read *The Union*, which has daily followed my peregrinations into exotic climes as well as being delivered at home. To me, except by the accident of birth, I am a New Hampshireite to the very core.

One can easily imagine my delight, when in 1940 it became possible to acquire a venerable house on the Parade in Greenland, nearly opposite the old parsonage in which I had passed such a happy young boyhood, and in being near Portsmouth, where many of my formative years were delightfully passed.

In looking about this group, I miss the faces of some of the medical giants of the days when I joined the Society. Barry and Parsons, of Portsmouth, Sullings and Walker, of Concord, McQuesten and Greeley, of Nashua, Flanders, Boutwell, French, Towne and Robinson, of Manchester, Jarvis, of Claremont, Prouty, of Keene, Staples, of Franklin, Smith, of Hudson, McGregor, of Littleton, Boynton, of Lisbon, Mitchell, of Epping, and Nute, of Exeter, to mention only a few. It is a real satisfaction to have known those men who have now passed away, and many other of the splendid physicians who then upheld the dignity of the New Hampshire profession as true followers of Aesculapius.

For these reasons, I am proud to accept the certificate of fifty-year membership.

As I wrote not long ago in *The Trosbadour*: "It is my hope that from my Greenland home, I can continue to look out over life calmly and steadfastly, until the world for me loses itself in the twilight of time and eternity."

The President then requested the delegates from other New England states to stand up and make themselves known.

The report of the House of Delegates was given by the secretary-treasurer, Dr Carleton R Metcalf.

Dr Robinson then presented the president-elect, Dr Ralph W Tuttle who acknowledged the applause of the audience.

President Robinson spoke as follows:

I wish to emphasize something that Dr Metcalf mentioned in the report of the House of Delegates, because I think it is one of the most important projects that the Society as a whole has to consider at the present time. Since we have a small society that is quite well integrated, we have an unusual opportunity to do exceedingly worthwhile and helpful work for the whole of the medical-care problem in this country, if we can undertake, on a voluntary insurance basis, the care of the indigent. The problem has been given some consideration, and it seems feasible to work out a scheme that will be satisfactory both to the welfare agencies and to the medical profession in the State, with the thought that we shall no longer have to be subject to the fees that we have charged for the rendering of such service, on a basis that belittles, in some ways, the medical profession. Of course, during the depression, it was perfectly proper, but because we established a

precedent, evidence that the present fee is being thought of as a proper fee for minimum medical care has grown up in the minds of the people that administer the program.

I should like to see that situation altered and to have the indigent cared for on the same basis as the minimal service charge that we make in the indemnity policy of the Blue Shield. Unfortunately, whereas the co-operation as a whole throughout New Hampshire has been good, there are certain physicians who have not believed that their own opinions regarding this means to take care of the costs of medical care are justifiable. If we could even get the co-operation of such men to the extent that they would be willing to try this as an experiment, so that we could get co-operation throughout the State, it would be possible for us to go ahead with this program. So long as there is any part of the State that is not co-operating, of course, it is apparent that the welfare agencies cannot take up their end of this particular scheme.

Another point that should be emphasized is that the Blue Shield plan that we are operating in New Hampshire is your plan, it does not belong to one physician but to every physician. The Blue Shield, which is simply the physical agent of the physicians in the State, can be altered as policies can be altered, on the basis of any justifiable and reasonable recommendations. You men should consider yourselves welcome to all the meetings of the professional sessions of that organization, and I believe that the directors of the organization want and hope for all possible criticism, because the only desire they have is to make the thing work, both to the benefit and satisfaction of the profession and to the satisfaction of the people that we try to take care of on that basis.

Dr Lendon Snedeker, of Boston, chairman of the Massachusetts Committee of the American Academy of Pediatrics, then spoke as follows:

I am speaking for Dr Colin Stewart, and I am sorry that he could not be here today. I am the executive secretary for the study of the American Academy of Pediatrics in Massachusetts. The study of child health services that the Academy has started is an attempt to obtain a physician's estimate of child health in the United States—facilities for serving children and their extent and location, such as those found in hospitals and in clinics and other health services outside institutions, including the schools. The study is also attempting to find out the contribution to health service to children made by doctors and dentists in every state, and is looking into the question of pediatric education, a topic that is being handled on a national level.

The completion of a project of this sort will take some time, probably another year and a half. Headquarters have been set up in Washington, and Dr John Hubbard, formerly of Boston, is the director for the study. A national committee, headed by Dr Warren Sisson, of Boston, is responsible for the over-all conduct of the study, for which a budget of nearly half a million dollars has been raised. Already, over thirty states have been organized and have started on the job, successful completion of the project appears possible.

Dentists are being reached through the state dental societies in general. Hospitals are being reached by the pediatricians and physicians around the country and the district health officers. The nurses and the doctors responsible for local health services are looking into clinics and extramural facilities.

The Academy has gone on record as being against the present health legislation before Congress, on which it believes this study, and the knowledge that it is being carried out, will have some deterrent effect. It also expects that the information disclosed by this study will be used on both national and state levels for laying a sound basis for any future health legislation that may come about. Much of the planning is up to physicians, and the way to achieve sound planning is for the doctors to get the facts. We are therefore asking you, when the questionnaire comes around, to give us facts on which we can say that this is what the doctors of the country are doing all the time for the children and the children's health services.

Dr Forrest J. Drury, director of the New Hampshire Veterans Service, spoke as follows:

I was glad this morning to hear Dr Bauer state that it was the policy of the present medical officials of the Department of Medicine and Surgery of the Veterans' Administration to keep the physician-patient relation and to provide care for veterans for their service-incurred disabilities, in their own communities and by their own physicians. That is exactly what we wish to do.

We shall authorize any physician registered in New Hampshire to care for any veteran in his community if that physician will co-operate with us in the very necessary paper work. I know that they will immediately say, "red tape," when they see a government form, but we have reduced that, we believe, to the irreducible minimum of forms, and I doubt that we will have any more forms to fill out than the Blue Shield has. We believe that our fee table is comparable to that of the Blue Shield.

If any veteran reports to any physician in the state with a letter that is sent to every veteran when his case has been adjudicated and grants service treatment for a service-connected disability, you are perfectly safe in going ahead and rendering the treatment, if you will report that fact to my office within five days after treatment is rendered. I must have that information. We work on a budget, and I must record the case on the budget within five days.

Veterans are entitled to hospital treatment in civilian hospitals in emergencies, but only for service-connected disabilities, the time consumed in getting the patient to a veterans' hospital and the distance must be considered to be dangerous. Such facts must be reported to my office within twenty-four hours. With outpatient reporting, five days are allowed. But when veterans are placed in hospitals without prior authority first, the case must be reported to my office within twenty-four hours. It is always best to get the authority beforehand.

We have sent letters to every physician on our list, with the probable exception of some men returning from the service, regarding payment of fees for examinations to determine the need for hospitalization. Until last October, examinations for non-service-connected disability could not be paid for. That meant that the doctors throughout the State were doing a great deal of work, and either the veteran paid for the examination or the doctor did not get paid for it. Under the new setup, however, and under a ruling last October, if a doctor is making an examination to determine the need for hospitalization, we can pay a fee of \$3.00, and if the call is made between 7:00 p.m. and 7:00 a.m. the fee can be \$5.00.

We recently sent letters to all physicians, telling them of our twenty-four-hour service. There is a memo on call of all night in the office and on Sundays and holidays. Therefore, the number of the Veterans' Administration can be called any time of the day or night, seven days in the week.

Another point Dr Bauer mentioned was the fact that these services exist in some states. There are two different setups. One is known as the New Jersey and the other as the Michigan setup. I hope that this society, some time in the near future, may see fit to set up a similar service. I prefer the Michigan to the New Jersey plan. The latter is not greatly different from the plan in New Hampshire, except that the society furnishes the names of physicians who have agreed to work on this plan. The Veterans' Administration sends out the forms. Under the Michigan plan, a contract with the Veterans' Administration takes care of everything. A physician in the veteran's community is designated to take care of the particular condition, the society then bills the Veterans' Administration. That, to my way of thinking, is the ideal setup. Under the Michigan plan, we get the names from the state society, instead of individually or from hospital staffs.

I should like to say that if there is any group of physicians, hospital staff, city or county society that would care to have me come at any time to any meeting, to tell them the whole story, I shall be very glad to do so.

Dr John C Leonard, a director of the Joseph Pratt Diagnostic Clinic in Boston, Massachusetts, then presented a paper entitled "Hypertension"

This was followed by a paper by Dr Clay R Murray, of New York, the subject being "Handling of Common Injuries to the Knee Joint"

Dr John T King, of Baltimore, professor of Medicine at Johns Hopkins University School of Medicine then presented a paper entitled "Acute Chest Episodes Caused by Pulmonary Embolism Differential diagnosis and treatment"

A financial report from the Trustees for the period beginning January 1, 1945, and ending December 31, 1945, was then presented, as follows

CASE 32431

PRESENTATION OF CASE

A fifty-four-year-old woman entered the hospital because of fecal vomiting

Five days before admission the patient had a sudden onset of severe, steady upper abdominal pain. She was seen by a physician about an hour later, when she was lying across a bed on a hot pad sweating and in such pain that she could not talk clearly but moaned and changed position frequently, attempting to void, urinate or vomit for relief.

The temperature was 96.4°F, the pulse 64 and the blood pressure 160 systolic, 90 diastolic. The patient had previously been known to have moderate hypertension. The abdomen was soft and nontender, and no scar was present. Peristalsis was minimal. Some time later she gagged in the hope of relief. Despite the administration of morphine, the steady pain continued through the night. On the following day the abdomen was still relaxed and nontender and almost silent. The patient was given 3 mg of Dilaudid and 0.1 gm of phenobarbital, and she slept. She was free of pain that evening and on the next day managed to retain a little food. Two days later she felt better and sat up, but vomited that evening. On the day before and on the day of admission she felt weak and vomited. The vomitus became fecal. Since the third day before admission there had been no pain or fever and the pulse had been slow.

On entry the patient had no pain. She was alert and talkative. The tongue was dry. The heart beat was regular at 80 per minute. The abdomen was slightly distended and tense, without spasms or tenderness. No masses were felt. Peristalsis was active and slightly high pitched, but was thought to be within normal limits. The uterus felt slightly enlarged on vaginal examination.

The temperature was 98.6°F, the pulse 72, and the respirations 20. The blood pressure was 140 systolic, 80 diastolic.

Examination of the blood showed a red-cell count of 4,500,000, with 11.4 gm of hemoglobin per 100 cc, and a white-cell count of 10,350, with 82 per cent

neutrophils many of which were band forms. The urine gave a ++ test for albumin, and there were 20 white cells and 10 red cells per high-power field. An abdominal film showed gas-filled loops of large and small bowel, one of which appeared distended.

A Miller-Abbott tube was inserted, and the patient passed a comfortable night. On the second hospital day there was slightly less distention, but peristalsis was definitely high pitched. She passed gas and a single, large stool containing old blood. The nonprotein nitrogen was 41 mg per 100 cc, the chloride 89 milliequiv per liter, the protein 6.3 gm per 100 cc, and the amylase 23 units per 100 cc. The white-cell count was 8100. On the third day she felt improved, the heart sounds were regular. The blood pressure was 110 systolic, 60 diastolic. The abdomen was distended, but softer. A soft nontender mass, 6 by 6 cm, was felt above the pubis. Peristalsis was normal. Another plain film of the abdomen showed dilated loops of small bowel in the central portion of the abdomen.

An operation was performed on the fourth hospital day.

DIFFERENTIAL DIAGNOSIS

DR MARSHALL K BARTLETT May we see the x-ray films?

DR MILFORD D SCHULZ The film made at the time of entry shows a gas-filled, dilated stomach and several loops of small bowel below it that are also distended with gas. Apparently some opaque medication was given by mouth some time before entry. The film made two days later, apparently when a barium enema had been given, shows no real obstruction in the colon. I think that there are still a few remaining loops of small bowel that are distended with gas. It looks as if there is some extrinsic pressure on the sigmoid, but there is no evidence of intrinsic disease.

DR BARTLETT Does the colon look normal?

DR SCHULZ Yes, except for the pressure on the sigmoid, which may be just an adjacent viscus.

DR BARTLETT To explain this picture we must find a condition that will account for the onset of extremely severe pain in the upper abdomen, without abdominal findings and without physical findings either at the time of onset or subsequently. The pain disappeared at the end of two days, and the patient had no further pain at any time. She subsequently developed symptoms that seem to point to a mild, incomplete intestinal obstruction. The symptoms did not include pain but she had vomiting that persisted and became fecal. She had peristaltic sounds that became high pitched and suggested a dilated bowel, and she had x-ray findings that are consistent with some type of obstruction. I am sure that if I had seen this patient at the onset of the original pain I should have considered stone in the biliary system, acute pancreatitis, perforation of a hollow viscus and possibly a dissecting aneurysm.

mesenteric thrombosis. It seems to me that we rule out a number of those conditions by the subsequent course of events. I do not see how a lesion of the biliary system or acute pancreatitis could have in this way. I do not believe that the subsequent intestinal symptoms would have developed on that basis.

How about a dissecting aneurysm? Again, I do not believe that the gastrointestinal symptoms could be accounted for in that way. At the end of seven days a large stool containing old blood was passed. Also, later on, a mass appeared that was not felt on admission — pelvic examination was done at that time and did not show it, it developed later. Could this have been something in the lower abdomen such as a twisted ovarian cyst or a volvulus of the sigmoid? I do not believe that either could account for the onset of such severe upper abdominal pain that disappeared completely in two days. It seems to me that we must find some lesion that will cause pain referable to the upper abdomen impairing the blood supply to the bowel in a manner that will allow some bleeding into the intestinal tract, so that that blood will later be passed as old blood, and a lesion that at the same time will give a picture of partial intestinal obstruction. I think that we can exclude the colon on the basis of the symptomatology, and I believe that we must place this lesion fairly low down in the small bowel. I believe that the likeliest thing that occurred in this woman was a mesenteric thrombosis. There are obviously a number of things that do not fit that picture, such as the lack of abdominal signs and the fact that the white-cell count was only 10,000. In spite of that, however, it seems to me that mesenteric thrombosis fits the picture better than anything else I know of, and I shall make that diagnosis.

DR. TRACY B. MALLORY: Is there anyone who would like to make a suggestion?

DR. MAURICE FREMONT-SMITH: Could the patient have had an intussusception that cleared up?

DR. BARTLETT: I think that she could have — one that was spontaneously relieved?

DR. FREMONT-SMITH: Yes, but in adults intussusception is usually associated with polyps or carcinoma.

DR. BARTLETT: It is usually associated with some tumor.

DR. MALLORY: One would probably expect previous attacks of incomplete obstruction in such a case.

A PHYSICIAN: How about internal hernia?

DR. BARTLETT: Do you mean by that a loop caught under a band?

A PHYSICIAN: Yes.

DR. BARTLETT: I think that she could have had that, but the symptoms were mild and the obstruction was incomplete. I also think that that would be less likely to give bleeding in the bowel.

DR. MALLORY: Dr. Welch, will you tell us your opinion before operation?

DR. CLAUDE E. WELCH: Perhaps I should first apologize for the surgical treatment. One might wonder why operation was delayed for four days after the patient came to the hospital. When she came in I could not even be sure that she had intestinal obstruction. She had a history of severe pain occurring three hours after drinking some cocktails, described by the physician, who had sampled them himself, as "sulfuric acid." She was so well at the end of almost a week's sickness that when she came to the hospital I thought that perhaps she had gastritis. We elected to treat her conservatively. At the end of twenty-four hours, it was obvious that there was obstruction. There really was fecal material coming out of the Miller-Abbott tube. We decided to give a barium enema and to study the situation further before exploration. As time went along the preoperative diagnosis favored by Dr. Arthur W. Allen was an intussusception because of the presence of the abdominal mass and the bleeding by rectum, together with intestinal obstruction. There were several votes in favor of the diagnosis of Meckel's diverticulum. In other words we all thought of the rare lesions and we also thought that, whatever the cause of the obstruction, it was a nonstrangulating type.

DR. MALLORY: Will you describe the operative findings?

DR. WELCH: When the abdomen was opened bloody fluid was immediately apparent. This mass that had been variously interpreted as fibroid uterus or some lesion associated with the bowel was a mass of gangrenous bowel that had been caught behind a simple band. As soon as the band was cut, the whole intestinal tract righted itself, but it was necessary to resect this entire loop of bowel. The patient had had no previous abdominal operation and no previous infections anywhere in the pelvis. We could not make out the cause of the bands but there were two present, one of which had caused the trouble.

CLINICAL DIAGNOSIS

Small-bowel obstruction

DR. BARTLETT'S DIAGNOSIS

Mesenteric thrombosis

ANATOMICAL DIAGNOSIS

Strangulation of bowel by adhesive band.

PATHOLOGICAL DISCUSSION

DR. MALLORY: The operative specimen we received showed nothing but gangrenous bowel. No cause was ever determined for the adhesive band.

DR. ALFRED KRAVES: What was the primary lesion?

DR MALLORY An adhesive band in a woman with no previous operation and no infection. There was secondary thrombosis of the mesenteric vessels.

DR FREMONT-SMITH If we knew that she had a band, should she not have been operated on at the beginning?

DR WELCH The point is that when she was first seen outside she should have been operated on at once. Then she would have been well and been home three weeks earlier. As time went on her condition became worse, and operation without preparation might have been fatal.

DR EARLE M. CHAPMAN I am sorry to have arrived late for this discussion, but perhaps I can clarify things a bit. This woman was quite well until a Sunday night when she drank the sour cock-tails at 6:00 and then had the agonizing abdominal pain that started about 10:00. I was awakened to see her at midnight, and the first thing I considered was gastritis severe enough to cause erosion or even perforation, but she had had such a normal abdomen without any scar on it that even a surgeon would have hesitated to operate at that time. I returned to Boston and she, being a Christian Scientist, was attended by the healer several times, but when fecal vomiting appeared the family overruled faith treatment and called in a neighborhood surgeon, who advised immediate operation. The family telephoned me — hospitalization here was advised, and I still think that the four-day delay in operation was wise treatment. At entry she was sick and vomiting and had an elevated nonprotein nitrogen and a low blood chloride, with supportive treatment she was in much better condition and made an amazing postoperative recovery.

CASE 32432

PRESENTATION OF CASE

A twenty-year-old girl entered the hospital complaining of a tumor on the collar bone of one month's duration.

The patient stated that she had always been in excellent health until about a month before entry, when she noted a small swelling located at the right sternoclavicular junction that was not tender or red and had not bothered her. It had increased rather rapidly in size, until it reached the size of a golf ball. There had been no weight loss.

Physical examination revealed a well developed and well nourished obese girl who did not appear ill. Positive physical findings were limited to the skin and the right clavicle, where there was a hard tumor, about the size of a golf ball, located on the superior portion just lateral to the sternoclavicular joint. It was slightly movable and was less hard on top than at the base, seeming to be attached to the clavicle.

The temperature was normal, and the blood pressure was 90 systolic, 60 diastolic.

Examination of the blood showed a red-cell count of 5,020,000, with 97 per cent hemoglobin and a white-cell count of 7500, with 52 per cent neutrophils, 38 per cent lymphocytes, 7 per cent monocytes and 3 per cent eosinophils. The red cells and platelets were normal. The blood Hinton test was negative.

X-ray films of the right clavicle revealed a destructive lesion, involving the proximal 5 cm of the clavicle with destruction of the cortex in the involved area, which extended up to the sternoclavicular junction. A film of the chest showed the lungs to be clear.

An operation was performed.

DIFFERENTIAL DIAGNOSIS

DR ERNEST M. DALAND The physical examination was essentially negative, with the exception of the lesion over the clavicle, which was revealed, on x-ray examination, to involve the clavicle. I believe that it comes down to a differential diagnosis of conditions arising in the clavicle.

May we see the x-ray films?

DR JAMES R. LINGLEY This is the lesion involving the medial end of the clavicle. I cannot add anything to the description given in the record. It appears to be destructive and has broken through the cortex.

DR DALAND Is there destruction of the upper cortex?

DR LINGLEY I think that there is probably destruction all the way through.

DR DALAND Has the lesion broken through the end of the bone?

DR LINGLEY The articular cortex looks intact. It has broken through anteriorly.

DR DALAND We must consider inflammatory lesions and tumor. The inflammatory lesions that could be involved include osteomyelitis, which I think we can rule out, since the white-cell count was normal and the patient was in fairly good general physical condition. Tertiary syphilis must be thought of immediately, because this is a frequent position for a gumma. The blood Hinton test was negative, and that fairly well rules out that diagnosis. Tuberculosis should also be considered, but it seems to me that one would expect to find complete destruction of the clavicle, including penetration through the articular surface. I think that a tuberculous process would have worked in around the sternoclavicular joint rather than have projected out as an external tumor. I believe that we can rule out any inflammatory condition.

The tumors most frequently encountered in the clavicle are probably the giant-cell tumors. In a giant-cell tumor one expects to find an expansile tumor with nearly equal vertical and horizontal diameters. Signs of expansion of the bone would have been observed before any break in the cortex, and the history would probably have been longer.

in one month with symptoms I think that we can rule out giant-cell tumor. An enchondroma could have occurred but again I think that there could have been evidence of bone expansion before rupture of the cortex, as well as a more distinct outline of the tumor. Osteogenic sarcoma is always a possibility in any bone, there is no bone where it cannot occur. The appearance of this lesion is suggestive of it, in that there was a break in the cortex on both sides, with an external tumor mass. There was no ray formation that I can make out and that is one of the characteristic signs of osteogenic sarcoma. There are no typical signs in an early case, however, and osteogenic sarcoma is a distinct possibility. I doubt that an eosinophilic granuloma could have produced an external tumor mass of this size with a bone lesion no larger than this. There is no note that there was any expansile pulsation, such as one expects in hemangioma destroying bone, and the external surface did not suggest hemangioma. We must consider metastatic cancer. Carcinoma of the breast can metastasize to the clavicle, as can many other types of carcinoma. This girl was only twenty, however, and the chances are against it. Physical examination apparently did not reveal any other disease suggesting a primary focus, and I think that metastatic carcinoma can be ruled out.

The probability is that this was a lymphoma. Lymphoma does occur in the clavicle as a solitary lesion. I recall a solitary lymphoma of the mid-portion of the clavicle that I resected about twelve years ago. I inserted a bone graft, and the patient remained well with no secondary lymphoma. The physical examination in the case under discussion also did not show any other sign of lymphoma. My belief is that this will turn out to be a lymphoma.

DR. LINGLEY: I should like to ask Dr. Daland if he would consider a Ewing tumor?

DR. DALAND: Yes, Ewing tumor should certainly be considered, and I cannot rule it out.

DR. TRACY B. MALLORY: What was your diagnosis, Dr. Lingley?

DR. LINGLEY: I thought that it was either Ewing tumor or lymphoma, and I put the former first.

DR. MALLORY: Dr. Hare, you originally read these films. What did you think about them?

DR. HUGH F. HARE: I thought that it was a lymphoma and put Ewing tumor second.

CLINICAL DIAGNOSIS

Lymphoma of clavicle

DR. DALAND'S DIAGNOSIS

Lymphoma of clavicle

ANATOMICAL DIAGNOSIS

Ewing tumor of clavicle.

PATHOLOGICAL DISCUSSION

DR. MALLORY: The operation mentioned in the record, at the point where the abstract terminates, was a biopsy, which showed a characteristic picture of a Ewing tumor. The patient was then given x-ray treatment by Dr. Hare. Perhaps he will tell us about that stage of the progress.

DR. HARE: When I first saw the patient following the biopsy, the swelling was considerably larger than a golf ball, being about the size of a lemon. We started treatment with large daily doses of 350 r, a total of 2800 r being given to the skin. It caused a skin reaction, and at that time we discontinued treatment. I saw the girl six weeks later, when the tumor had decreased somewhat in size.

DR. MALLORY: About two months following the x-ray treatment the patient again entered this hospital, and it was decided to resect the clavicle. That was done, and I have a photograph (Fig. 1) that I shall show you. The proximal end of the clavicle lies

FIGURE 1

to the right. A large cystic cavity filled with blood and necrotic tissue can be seen. We made many sections throughout that area. We were unable to find any remaining trace of tumor. So far as the morphologic evidence is concerned, the x-rays had apparently completely destroyed the neoplasm.

One always has the alternative of x-ray treatment or surgery in these cases. Does anyone wish to express an opinion in this case? This patient was given a double chance, since she received both forms of treatment in succession.

DR. GRANTLEY W. TAYLOR: This patient's family was anxious that something further be done if possible to improve her chance of cure, because the prognosis given to them following biopsy and x-ray treatment had been pessimistic. Since the tumor was still present and the x-ray evidence of destruction showed a continuing process in the clavicle, it seemed worth while to consider excision of the clavicle. The skin had recovered from the initial radiation reaction and had not yet undergone the late changes that jeopardize healing following surgery through a radiated area. With these facts in mind, the entire clavicle was removed, including the periosteum and the muscular attachments. The pa-

tient made an excellent recovery from operation, and the wound healed primarily. She has returned to work and has excellent function of the arm. There is no evidence of metastasis or recurrence at the present time.

DR. RICHARD H. WALLACE: I should like to ask about the possibility of recurrence with this sequence if the clavicle had not been removed. What assurance is there that there might not have been a few viable cells?

DR. MALLORY: Frankly speaking, none. It would be impossible to rule that out with certainty.

That there had been massive and apparently complete destruction of tumor is all that I can say.

DR. WALLACE: Would there be reasonable assurance that it might not recur, since there was no microscopic evidence of tumor?

DR. MALLORY: I should prefer to have a radiologist's opinion. It is my impression that, in a fair number of these cases treated by x-ray, there has been no recurrence even in the face of metastases. Is that correct?

DR. LINGLEY: Yes, we have had several such cases.

The **JOURNAL** does not hold itself responsible for statements made by any contributor.

COMMUNICATIONS should be addressed to the *New England Journal of Medicine*, 8 Fenway, Boston 15, Massachusetts.

"A HUNDRED YEARS AGO"

IT HAS long been a custom of certain of our esteemed, if more youthful, contemporaries, particularly those addicted to the daily dissemination of current events, to publish a department that comments briefly on the happenings of an otherwise forgotten era. Thus each day there appears in subdued tones, betokening the softening influence of time, the abbreviated news stories of a quarter century ago, reminding the reader that there has been a past, however colorless, in addition to a troublesome present and a hypothetical future. In view of these attempts to link the present with the past, the *Journal*, sturdy survivor of a hoarier

age,—for even the *Boston Herald* came in only with ether,—has decided to make its own contribution to this factual anthology with its scarcely rivaled opportunities for chronological research, it has determined to dig more deeply into the archives of antiquity and bring forth from time to time, or at approximately lunar intervals, brief excerpts from its own files of a century ago.

The first article of the series appears elsewhere in this issue of the *Journal*, and it should be noted that the leading item in these abstracts of October, 1846, comments on that anesthetizing preparation with the aid of which, no doubt, our previously mentioned young journalistic contemporary was eaned. Even then, the *Journal* was in the fore with the publication of medical discoveries of importance. Some of these excerpts deal with truths that seem to be permanent, which is less often the case with scientific advances than it is with some of the basic principles of our art. Thus, with the reference to the poor chirography among medical men, this is as true today as it was a century ago, and is due, obviously, to the policy of putting it up to the apothecary to compound the prescription the way it ought to be.

These miscellaneous abstracts will serve other purposes than to entertain and to amuse. They will remind us that former days have had their pioneers, their heroes, their men of stature, that the achievements of today are built on the foundations that untold centuries of achievement laid down. While we are entertained, let us also be chastened, for one day we, too, will be of a century that has passed.

The *Journal* is fortunate in that Dr. Reginald Fitz has consented to compile this column. A student of medical history, Dr. Fitz brought to his term of office as president an unusual devotion to the interests of the Massachusetts Medical Society, as well as a knowledge of its traditions.

THE PATIENT AND THE TRUTH

THE question whether a patient with malignant disease should be told the truth, the whole truth and nothing but the truth is not easy to answer. The

subject is thoroughly discussed in two papers in the June issue of the *Annals of Internal Medicine*.^{1,2}

The chief difficulties in answering this question arise from the facts that the psychologic make-up of one patient differs from that of another, that legal responsibility is involved and, finally, that the physician himself does not always know what is the truth — the best may be mistaken. A family will forgive him if he says that the patient is going to live and the patient subsequently dies — for all men die, but the physician will never be forgiven if he predicts without qualification a fatal outcome and the patient then proceeds to get well. Furthermore the intricacies of medical terminology are such that the doctor is often forced — in telling the truth — to use lay terms that are, in themselves, scientifically inaccurate to convey to the patient his idea of the truth, and thereby he may defeat his own purpose and end merely by confusing or, from a legal point of view, by misleading the patient.

Certain principles seem reasonably well established. Some responsible friend or relative of the patient must be apprised of the facts in so far as they are known. No operation, unless it be an emergency life-saving measure, may be done without the patient's consent. No misstatement of facts or evasive answers may be given if the purpose is to serve the physician's personal interests or financial gain, nor may an operation be performed for like reasons. A physician may be liable if he makes a positive but erroneous diagnosis. It is rather generally agreed that a doctor suffering from one or another form of malignant tumor should be so told, but from this point on there is no unanimity of either legal or non-legal opinion regarding how much or how little should be said.

It may seriously be questioned whether it "usually does good to patients to tell them that the outlook is hopeless."¹ It seems truer that "an insight gained gradually is less likely to cause intense mental anguish than knowledge gained abruptly of one's imminent demise."² A few there are who can face the truth with equanimity. There are some, of course, who must be told the truth because their personal or professional responsibilities are such that their affairs must be put in order. But even here,

if some responsible member of the family or some close friend has been informed about the facts, it is not often that the patient need be directly told by the physician.

It may be necessary or advisable to tell a given patient that he has cancer in order to persuade him to undergo what is believed to be the necessary therapeutic measures, but at the same time the word "cancer" may so frighten a patient that he refuses treatment, — so imbued is the lay mind with the idea that cancer is incurable, — and the use of such a word as "tumor" or "mass" often serves better to adjust the patient's therapeutic future.

The question whether a physician if asked by a patient with cancer "Have I cancer?" must necessarily answer "Yes" is a moot one. It is doubtful whether a suit would lie were the physician to skillfully by-pass the question, provided, of course, that some responsible member of the family knew the facts.

The question of prognosis is also a difficult problem. At best one can deal in broad generalities. Neither the average nor the mean necessarily applies to the individual case unless the extremes are so close to each other that the difference is negligible. A patient with malignant or pseudomalignant disease is usually satisfied with the statement that the condition is a serious one, that certain therapeutic measures are advisable and that benefit will accrue. As time passes the patient either fails progressively without fully realizing it or, by himself, comes to recognize that he will have the disease all his life. From that point the transition to a realization that he will die of the selfsame disease is an easy one, and the experienced physician is able to tell when such knowledge has been gained. When it has, the patient seldom speaks of it, the doctor need not.

If a physician has followed a course sincerely designed for the patient's best interests, if he has told some responsible person the facts and if he has informed the patient that the condition is a serious one, no court would judge him derelict in his duty.

HUNDRED YEARS AGO

Strange stories are related in the papers of a wonderful preparation in this city, by administering such a patient is affected just long enough and just powerfully enough to undergo a surgical operation without pain — Benjamin Waterhouse, M D, died recently at the patriarchal age of ninety-two at his residence in Cambridge. During the active part of his life very few physicians have held a more conspicuous place in the public observation. A lecture which he delivered about 1805 to the Harvard undergraduates on the custom of smoking cigars is supposed to have had great influence in whatever diminution of that practice was consequent on its publication. He was an early and decided advocate for the introduction of the practice of vaccination into this country and always esteemed it one of his proudest laurels that he was designated the American Jenner — Cholera morbus is spoken of as being quite fatal in the eastern part of New Hampshire. — As a fraternity medical men are proverbial for their bad writing. Some of the manuscripts sent to us would puzzle the chirographical professor to determine whether they were written in English, Chinese or Cherokee. A physician who cannot write should not be allowed to practise, and a man who can write and only scrawls should be regarded as committing a criminal offence — Dr Daniel Drake, of Cincinnati, reports "I have lately assisted in the *post mortem* examination of two patients who died after several weeks of illness with symptoms answering well to Louis' description of Typhoid Fever. This fever may be among our increasing diseases. If so, it is entitled to great attention, just as an invading army should be more vigilantly watched than one which is retreating. Can anyone tell whether those cases of remittent bilious fever which in their latter stages exhibit typhoid symptoms are accompanied by lesions of the ileum?" — A boy seven years old swallowed an open penknife three inches long. The symptoms afterwards were slight. The treatment enjoined was perfect quietude, fomentations, saline febrifuges, sedatives, the occasional exhibition of slight aperients, castor oil etc. On the morning of the sixth day the knife appeared with an evacuation, blade downward, somewhat corroded and not at all improved in appearance by its change of residence. — The increasing population of Boston demands corresponding charities to meet the necessities of the sick and infirm poor. A conviction that another infirmary was required led to the

recent opening of one at 425 Washington Street. This is to be open at all hours so that those who are least able to walk from a remote section of the town will be certain of finding someone to give them desired advice. John B Walker, M D, takes charge of the department of surgery, C E Buckingham, M D, E H Clarke, M D, S Kneeland, M D, and W Henry Thayer, M D, will in turn be in attendance in the management of the medical labors. All operations will be performed gratuitously when necessary and bandages, apparatus etc freely given — A lady ninety years of age residing at Cold Spring has recently cut four front teeth, being the third set, and her eye-sight has so far returned that she can see without glasses. — Some villain has discovered a new agent of iniquity in the way of drugging cigars with narcotics. A boy of five picked up a cigar partly smoked and gave it to a journeyman tailor. He lighted it but after a few puffs, experiencing some uneasy sensations in his head, threw it down. The little boy then tried it, exhibited all the symptoms of violent poisoning and died eighteen hours later. Three professional gentlemen who saw him opined that the cigar had been drugged with some virulent narcotic — A new remedy for strangury is announced. Take 40-60 bees in a tea-cup, pour one gill of boiling water on them and cover the cup securely. When it has stood for about twenty minutes, pour off the infusion and let the patient take the whole as a draught. It is supposed that the material which gives efficacy to the bee tea is the virus ejected by its sting. It remains to be seen whether this virus may not be collected and preserved so as to be employed when the bee itself is not to be obtained — A barrel containing several parts of a human skeleton was found floating in the upper basin of the Mill Dam, Boston, by some boys last week — A Swiss journal states that the bulb of the dahlia when dressed like the potato affords an excellent article of food — We perceive that Medical Societies in several States have already elected delegates to the great convention to be holden in Philadelphia in May next. If we may judge from the spirit manifested at the last convention, we presume that medical men of respectability who may be present will not only have seats accorded to them but the liberty of discussion if they desire it — Extracted from the *Boston Medical and Surgical Journal*, October, 1846

NEW HAMPSHIRE MEDICAL SOCIETY

DEATH

WIGGIN — Henry M Wiggin, M D, of Whitefield, died June 29. He was in his seventy-eighth year.

Dr Wiggin received his degree from Boston University School of Medicine in 1895.

His widow and two sons survive.

MISCELLANY

DR BARTON AWARDED LEGION OF MERIT

Dr Walter E Barton, superintendent of the Boston State Hospital, was recently awarded the Legion of Merit Medal for his work with the Office of the Surgeon General in the rehabilitation of Army patients. Active for fifteen years in the Massachusetts State Medical Service as a psychiatrist, Dr Barton received the award for his work in organizing and developing the reconditioning program for convalescing patients. As a lieutenant colonel in the Army Medical Corps, his specific services in shaping the doctrine and policy of the four interrelated services of occupational therapy were instrumental in furthering Army medical care.

NOTE

Dr Lloyd C Fogg, formerly associate professor of microscopic anatomy, Boston University School of Medicine, has been appointed registrar of the School. Dr Fogg assumed his new duties at the beginning of the current academic year.

CORRESPONDENCE

ERRATUM

To the Editor I wish to call attention to an error that crept into my manuscript "Surgery of the Innominate Artery," which was published in the July 18 issue of the *Journal*.

On page 74, near the bottom of the first column, I referred to "Burrell, of Philadelphia." Actually, Dr Burrell was a clinical professor of surgery at Harvard and a resident of Boston. The error came about because the transcription in which his case was published was for the meeting of the American Surgical Association held in Philadelphia in 1895. Dr David Cheever pointed out this error to me.

789 Howard Avenue
New Haven, Connecticut

GUSTAF E. LINDSKOG, M D

NOTICES

ANNOUNCEMENTS

Dr Edward A Adams announces that Dr Robert S Thomson is associated with him for the practice of general surgery at 44 Oliver Street, Fitchburg.

Dr Norman H Boyer, having returned from military service, announces the reopening of his office at 29 Bay State Road, Boston.

Dr Thomas E Chretien has returned from naval service and announces the opening of an office for the practice of general medicine at 435 Wolcott Street, Auburndale.

Dr Clito R Damiani announces the opening of an office at 16 Norwich Street, Worcester, for the practice of dermatology.

Dr William H Holtham, having returned from military service, announces the reopening of his office for the practice of urology at 270 Commonwealth Avenue, Boston.

Dr Philip A Isaacson, having returned from military service, announces the opening of his office for the general practice of medicine at 717 Main Street, Fitchburg, Massachusetts.

Dr G S Nossaff, having returned from military service, announces the opening of an office at 38 Congress Street, Milford, succeeding Dr Perry E Joslin.

GREATER BOSTON MEDICAL SOCIETY

A meeting of the Greater Boston Medical Society will be held in the auditorium of the Beth Israel Hospital on Tuesday November 5, at 8 15 p m. Dr Reginald H Smithwick will speak on the subject "Operative Measures for the Relief of Hypertension."

CUTTER LECTURE

The Cutter Lecture on Preventive Medicine will be given by Sir Lionel Whitby, Regius Professor of Physics, University of Cambridge, England, at 5 p m on Wednesday, November 6, in the Amphitheater of Building D of the Harvard Medical School. His subject will be "The Hematological Effects of Irradiation."

The medical profession, medical and public-health students and others interested are cordially invited to attend.

SUFFOLK DISTRICT MEDICAL SOCIETY

The fall dinner meeting of the Suffolk District Medical Society will be held at the Harvard Club of Boston on Saturday, November 9, at 7 00 p m. Dr Shields Warren will speak on "The Physiological and the Pathological Effects of the Atomic Bombs," and Dr Joseph C Aub will speak on "Isotopes in Clinical Research."

Members of the district society and their wives, as well as young people of high-school and college age whose parents are members, are cordially invited to attend. Tickets for the dinner and cocktails (\$3 00 per person) must be purchased in advance by sending cash or a check to Dr Richard S. Eustis, 319 Longwood Avenue, Boston 15, before November 7. After this date other members of the Massachusetts Medical Society, their wives and young adult members of their families, may apply. Cocktails will be served at 6 30 p m.

AMERICAN CONGRESS ON OBSTETRICS AND GYNECOLOGY

The third American Congress on Obstetrics and Gynecology will be held September 8 to 12, 1947, in St. Louis, Missouri. All the meetings and the scientific and technical exhibits will be held in the Municipal Auditorium.

Although the third congress is similar in scope and program to the two previous meetings, it will be larger in every way. The program is being made up to appeal to specialists in obstetrics and gynecology, to general practitioners interested in those fields, to hospital administrators and to nurses, as well as to public-health physicians and nurses.

The morning sessions of the congress on September 12 will be given over entirely to the National Federation of Obstetric and Gynecologic Societies. An evening speaker of national prominence will present his viewpoints to a joint meeting of the congress, the federation and the general public.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, OCTOBER 31

FRIDAY, NOVEMBER 1

ISLET-CELL TUMOR OF THE PANCREAS WITH HYPERINSULINISM*

A Report of Six Cases

ALEXANDER MARBLE, M.D.,† AND LELAND S. MCKITTRICK, M.D.‡

BOSTON

ALTHOUGH in recent years many publications regarding patients with pancreatic islet-cell tumors have appeared, the condition is sufficiently frequent to make additional reports desirable. Since 1938 we have observed 6 patients in whom the diagnosis was verified at operation performed by one of us (L. S. McK.). Our experience with these patients forms the basis for the present paper. This report is particularly worth while at the present time because it provides a four-year to seven-year postoperative follow-up study of the patients concerned. In 5 of the 6 cases removal of a single adenoma at operation resulted in relief of symptoms that has persisted to date. In 1 case death followed a few weeks after operation, which disclosed an islet-cell carcinoma with multiple metastases in the liver. A summary of the data in these cases is given in Table 1.

CASE REPORTS

CASE 1. P. F., a 16-year-old girl was first seen on November 28, 1938. She had been well until the summer of 1933, when she began to have occasional spells of stupor that progressed into definite unconsciousness. In July of that year she was seen in the outpatient department of a children's hospital and in the next month at another hospital, where, while waiting for an examination after having missed the noonday meal, she fainted, remaining unconscious for about an hour, during this period she had a few convulsive twitchings of the shoulders and face and voided involuntarily. She was admitted for observation to the hospital, where she remained from August 18 to September 14. The fasting blood-sugar concentration was consistently low (of twelve determinations, ten were below 60 mg. per 100 cc., including five that were below 50 mg.). An attack of coma brought on by starvation was relieved by the intravenous injection of glucose, consequently the diagnosis of hyperinsulinism was made, and the patient discharged with instructions regarding diet. She was readmitted on January 8, 1934, because in the week before entry attacks had occurred far more frequently than

previously. During this admission, after extensive studies, abdominal exploration was carried out. No tumor was found, a small section of the tail of the pancreas removed for histologic examination was found to consist of normal tissue. The postoperative course was uneventful, and the patient was discharged on February 27 with instructions to follow a diet restricted in carbohydrate. The patient was subsequently seen in the Out-Patient Department on only one occasion, on March 16, 1934, when she reported that she had had no attacks since discharge from the hospital.

The patient was free from obvious attacks until August, 1938, when she suffered a recurrence of spells of drowsiness and weakness, particularly after an overnight fast. These symptoms were relieved by food or glucose. The attacks increased in frequency, and on November 8 she was taken to a third hospital in a deep stupor. On admission the blood-sugar concentration was 38 mg. per 100 cc. The patient was revived from her stuporous condition by means of concentrated glucose intravenously and sweetened orange juice orally. During a stay of 16 days in the hospital she was kept from hypoglycemia by frequent feedings. Roentgenograms of the chest, skull and abdomen gave normal findings, films of the teeth showed evidence of considerable infection. Electroencephalograms were thought to suggest that the patient, in addition to the overactivity of the sugar-disposing mechanism, had an epileptoid condition of cerebral dysrhythmia.

The patient was admitted to the New England Deaconess Hospital for further study on January 3, 1939. In the preceding days occasional attacks of hypoglycemia had continued. She had taken a bedtime lunch routinely, as well as orange juice at 5:00 o'clock each morning. Physical examination showed a small thin, underdeveloped girl who seemed pale and listless. The body weight was 107 pounds (48.6 kg.) and the height 4 feet 9½ inches (147 cm.). The teeth were poor, there was marked caries despite the extraction of 5 teeth a few days previously. The heart was normal in size and regular in rhythm and over the whole precordium a prominent systolic murmur was audible. The abdomen was normal, there was a long healed operative scar in the left upper abdomen. The blood pressure was 104/70.

Questioning revealed that there had been no significant illnesses before 1933 and no abnormality except that discussed above. The father, mother, a brother and two sisters were living and well.

After 8:00 o'clock on the morning following admission the patient became increasingly drowsy so that by the time breakfast was served—45 minutes later—she was unconscious. The blood-sugar concentration was 28 mg. per 100 cc. The administration of glucose intravenously brought about prompt relief. During the next 2 weeks the patient was kept on a diet that included from 199 to 315 gm. of carbohydrate daily. By means of feedings between meals she was kept from hypoglycemic attacks.

The results of the glucose-tolerance tests in this case—and in the other 5 cases of the series—are shown in Table 2.

Examination of the urine showed no albumin, bile, diacetic acid or sugar, and examination of the sediment was nega-

*From the George F. Baker Clinic (Elliott P. Joslin, M.D., medical director), New England Deaconess Hospital and the West Surgical Service, Massachusetts General Hospital.

†Instructor in medicine, Harvard Medical School physician, New England Deaconess Hospital.

‡Associate in surgery, Harvard Medical School, surgeon-in-chief, Palmer Memorial Hospital, visiting surgeon, Massachusetts General Hospital.

*A detailed account of the early history studies and findings at the first operation in this case was presented by Boone¹ in 1934.

tive Examination of the blood revealed a red-cell count of 4,660,000, with a hemoglobin of 82 per cent (Sahl), and a white-cell count of 10,150, the blood smear was essentially normal. The blood Hinton reaction was negative. The cholesterol content of the blood plasma was 163 mg per 100 cc. The bromsulfalein test of liver function gave normal results. Roentgenograms of the skull and chest and of the region of the kidneys, ureters and bladder were normal. A gastrointestinal series was likewise normal, there was no change in the size and shape of the duodenal loop.

In view of the exacerbation of hypoglycemic attacks, it was thought justifiable to carry out a second pancreatic exploration despite the negative findings 5 years previously. Consequently, on January 16, exploration was performed under ether anesthesia through a long, curved transverse incision just above the umbilicus through both rectus muscles of the type used by Whipple.³ Because of adhesions that had obliterated the lesser peritoneal cavity, painstaking dissection was necessary to free the stomach from the pancreas. The entire anterior aspect of the pancreas was exposed, from the extreme tip of the tail to the portion of the head that was visible anteriorly, the body and tail were then completely freed posteriorly. Inspection and careful palpation revealed no tumor in the part of the pancreas thus exposed. Attention was next directed to the remainder of the head of the pancreas. The entire head, together with the loop of duodenum, was elevated as much as the important vascular structures permitted. With the thumb and fingers of the examiner grasping the head of the pancreas, it was possible to feel a small tumor completely within pancreatic tissue. An exploratory incision brought into view a somewhat lobulated, encapsulated, reddish-purple nodule, which was completely removed, the rest of the organ was again palpated for other tumors, none being found.

The following was the description of the nodule by the pathologist:

The tumor was a delicately encapsulated, reddish-brown, moderately yielding nodule, almost spherical, measuring 1.2 by 1.1 by 0.9 cm. On cross section it was found to be soft, moist, pale and reddish brown, with a few fine, gray foci indefinitely marked. Microscopic examination showed adenomatous tissue made up of beta cells.

The postoperative course was uneventful. Blood-sugar values during the first 48 hours ranged from 120 to 310 mg per 100 cc, but during most of this time the patient was receiving glucose solution intravenously. From the 2nd postoperative day on, all random blood-sugar values were uniformly normal. Electroencephalograms taken after operation were normal. The patient was discharged from the hospital on February 4, in good condition.

On assays for insulin content the tissue was found to contain approximately 7 units of insulin per gram, or about twice the amount present in normal pancreatic tissue.*

After operation the patient continued in good condition. There were no attacks suggesting hypoglycemia, random blood-sugar values were normal and glucose-tolerance tests showed a normal response. The blood-sugar concentration on May 18, 1946, after an overnight fast, was 84 mg per 100 cc. When last heard from in August, 1946, over 7 years after operation, the patient had continued to feel well.

CASE 2 L. H., a 49-year-old woman, was first seen on June 20, 1939. She had been well until January, 1931, when she began experiencing attacks of extreme weakness and drowsiness. During such periods she was unable to speak, felt listless and complained that the hands were cold and numb.

Examination revealed no satisfactory cause of the difficulty, but the patient seemed to improve on a high-carbohydrate diet, with frequent feedings, during spells of weakness she obtained relief by drinking orange juice. With the added food she gained in weight from 165 pounds in 1931 to 214 pounds in 1934. In May, 1934, the spells became severer. The patient was admitted to a hospital, where blood-sugar values as low as 42 mg per 100 cc were found. A glucose-tolerance test carried out for 4 hours was reported to be entirely normal. She progressed fairly well until November, 1938, when she was readmitted to the hospital with the same complaints. The weight at that time was 220 pounds, and the patient stated that for the preceding 4 years she had had

one or two attacks a week, which were relieved by orange juice. A glucose-tolerance test carried out on November 1 showed the blood-sugar concentration after fasting to be 59 mg per 100 cc, following the administration of 170 gm. glucose the value after the 1st hour was 183 mg, after the 2nd hour 155 mg and after the 3rd hour 133 mg per 100 cc. During the hospital stay in November the amount of carbohydrate in the diet was varied from 60 to 225 gm daily, with no significant change in the condition except a loss in weight to 187 pounds.

The patient was admitted to the New England Deaconess Hospital on June 20, 1939. Physical examination showed an obese woman, the body weight was 186 pounds (84.5 kg.) and the height 63 inches (161 cm). The heart was normal in size and regular in rhythm, and a moderately loud systolic murmur could be heard over the precordium. The lungs were clear, the abdomen normal, and the blood pressure 144/82. Examination of the blood revealed a red-cell count of 4,740,000, with a hemoglobin of 77 per cent (Sahl), and a white-cell count of 14,000, with a normal blood smear except for slight acromia. Examination of the urine showed 10 mg of albumin per 100 cc, no sugar, diacetic acid or bile and a normal sediment. The bromsulfalein test of liver function gave normal results, and the blood bilirubin was 0.2 mg per 100 cc. The basal metabolic rate was -10 per cent. A blood Hinton test was negative.

The past history was essentially noncontributory. The family history was irrelevant, the patient had three grown children — one son and two daughters — living and well.

During the first 9 days in the hospital the patient appeared generally dazed, with slow reactions. Blood-sugar values as low as 31 mg per 100 cc were found. Roentgenograms of the skull were normal, as was a gastrointestinal series, in which the duodenal sweep seemed of normal extent.

Exploratory laparotomy was carried out on June 28, under ether anesthesia, through a transverse incision. The pancreas was easily exposed and freed from its attachment without difficulty, disclosing a small nodule at about the midportion of the organ on the anterior aspect near the lower border. Incision showed it to be a soft, friable, purplish tumor that on section was found to include considerable grayish necrotic material. The tumor was well encapsulated and could be completely removed, although because of its friability, during the removal it broke into two parts, the larger of which was 8 mm in diameter. Careful inspection and palpation failed to disclose any other tumors. Microscopic examination showed the nodule removed to be an islet-cell adenoma made up chiefly of beta cells. Assay showed the tumor to contain more than 100 units of insulin per gram.

The postoperative course was uneventful, and the patient left the hospital in good condition on July 20. Except for fasting blood-sugar values of 130 mg and 120 mg per 100 cc, for the 1st and 2nd days respectively after operation, all values postoperatively were normal and the patient was entirely free from hypoglycemic attacks. A glucose-tolerance test carried out on July 18 gave entirely normal results (Table 2).

The patient reported for examination on October 18, 1939. May 21, 1940, and May 29, 1942, when questioning revealed no symptoms suggesting hypoglycemia and careful study, including glucose-tolerance tests, yielded results within normal limits except that, in general, blood-sugar values 4, 5 and 6 hours after the administration of glucose tended to be and 6 hours after the administration of glucose tended to be subnormal or toward the lower limit of normal. The patient remained entirely asymptomatic, however, and blood-sugar values after an overnight fast were normal. In the last letter received from her, dated August 4, 1946, she stated that she had been well and active.

CASE 3 F. P. H., a 58-year-old woman when first seen on September 15, 1938, had been well until June, 1935, when she had had an attack of fainting followed subsequently by periods of coma during which she slept 12 to 48 hours. At times she suffered blankness of vision. In 1936, adopting a suggestion from a newspaper article, she began to take sugar for the attacks and found that this gave relief. The periods of drowsiness, mental confusion and speech disturbance continued, however. The patient first consulted a physician on October, 1937, when fainting spells were occurring once or twice daily and often on awakening at about 5:00 a.m. She entered a hospital on June 23, 1938. The fasting blood sugar,

*All assays in these cases were performed by Mr. George B. Walden, of the Research Laboratories of Eli Lilly and Company Indianapolis to whom frozen portions of the tumors were sent.

†Previously reported in part by Gray.⁴

was 27 mg per 100 cc 2 days later, was subsequently to average about 45 mg. The patient was put on a low-hydrate, low-protein, high-fat diet, on which she did well for a time, but returned later because of recurrence of symptoms and the need of increasing the feedings to every 3 hours to prevent attacks. A diagnosis of probable cell tumor was made.

During the first admission to the New England Deaconess Hospital in September, 1938, studies confirmed this diagnosis. Fasting blood-sugar values as low as 30 mg per 100 cc obtained, and on one occasion, after exercise, a value of 1 mg was reported. Roentgenograms of the heart, lungs, and gastrointestinal tract were normal. Examination of ocular fundi gave normal findings. The basal metabolic rate was -7 per cent. The blood calcium was 10.1 mg and blood phosphorus 3.8 mg per 100 cc. The bromsulfalein of liver function gave normal results. An electrocardiogram was essentially normal. The blood Hinton reaction was negative.

Her past and family histories were irrelevant. Review of x-rays revealed nothing of consequence except for "nervousness" and for exertional dyspnea noted since a gain in weight. Physical examination showed an obese, healthy-appearing woman. The body weight was 188 pounds (85.5 kg), and height was 63 inches (161 cm). Examination of the heart, lungs and abdomen was essentially negative, and the blood pressure varied from 115/65 to 160/80.

Abdominal exploration was advised but was refused by the patient. Although she promised to return soon for operation, actually she did not re-enter the hospital until September 12, 1939. Within a month or so following discharge in 1938, she had fallen at home, suffering injuries that kept her bed for 28 weeks. The hypoglycemic attacks had continued during the year and had been particularly frequent and marked after resumption of physical activity. Unless food was taken about every 3 hours, vision became blurred and mental dullness, stupor, unconsciousness and, at times, convulsions followed. During the 2 weeks prior to the second admission a special nurse had been in attendance in the home and had awakened the patient every 2½ hours for feedings during the night.

Physical examination showed the patient to be even more obese than at the former visit—205 pounds (92.3 kg), as compared with 188 pounds (85.5 kg) a year previously. The heart seemed normal in size and was regular in rhythm, a slight generalized systolic murmur could be heard. The lungs were clear, and the abdomen normal to palpation. The fasting blood sugar on the morning after admission was 29 mg per 100 cc. Examination of the blood showed a red-cell count of 4,540,000, with a hemoglobin of 86 per cent (Sahli), and a white-cell count of 12,700, with a normal differential. The urine contained a trace of sugar but no albumin, bile or acetic acid, and the sediment was essentially normal. The food nonprotein nitrogen was 31 mg, and the cholesterol content of the blood plasma 153 mg per 100 cc (the free cholesterol was 35 mg per 100 cc).

It was soon evident that unusual precautions were essential to keep the patient from becoming hypoglycemic. The blood-sugar values were so low and the attacks were so frequent, despite careful supervision, that early exploratory operation was carried out 4 days after admission. A transverse incision was made, and the pancreas exposed through the gastrotomy omentum. After mobilization of the organ a tumor about 1.5 to 2.0 cm in diameter was visible toward the tip of the head of the pancreas, which was adherent to adjacent structures, lay high and was accessible only with great difficulty. Finally it was freed, and resection of the tip of the organ was carried out, although not more than 3.0 to 3.5 cm of the pancreas was removed. The tumor was firm and seemed to infiltrate surrounding tissue, suggesting a malignant process. The liver was studded with grayish-white nodules varying in diameter from several millimeters to about 2 cm. A wedge from one of these nodules was excised and examined.

The postoperative course was extraordinary. For the 1st week blood-sugar values were within normal limits. Then on September 23, a week after operation, small amounts of sugar appeared in the urine, and a capillary blood-sugar value at 11:00 a.m. was 200 mg per 100 cc. In the next 3 days glycosuria and glycemia increased, so that urine tests for sugar by the Benedict method ranged from yellow to red, and the fasting blood sugar on September 27 was 247 mg per 100 cc.

Consequently, treatment with protamine-zinc insulin was instituted and continued for a total of 29 days in a dosage of 12 to 16 units daily before breakfast. The food intake during this period was variable because of the patient's condition, the amount of carbohydrate taken daily averaged 149 gm, that of protein 41 gm and that of fat 35 gm. On this regime, fasting blood-sugar values varied from 120 to 150 mg per 100 cc. From October 25 until the patient's death on November 3 no insulin was used.

In the few days immediately following operation the patient's general condition was much improved. Then, however, crepitant rales were heard at the lung bases, silant rales were heard throughout the chest, and moderate fever was present. Roentgenograms showed patches of bronchopneumonia in the lower half of both lung fields. From the day of operation, September 16, until September 19, the patient received a constant infusion of glucose into a vein at the elbow of the right arm. An area of induration and tenderness developed above the antecubital space on the outer aspect of the arm, the inflammation gradually subsided but healing never entirely took place, and on October 21 the right arm was more swollen than before. At that time generalized anasarca also developed. The right external jugular vein became palpable and tender. The clinical impression was that the swelling of the right arm did not represent an infection, but rather edema secondary to venous thrombosis. Later however, a hard, slightly tender area about 5 cm in diameter developed in the right lower axilla, on October 10 this was incised, allowing 60 to 90 cc of thick pus to drain.

Immediately after the abdominal operation the body temperature rose to a maximum of 103°F and then ranged between 99 and 101°F for 4 or 5 weeks before completely subsiding. The operative wound in the abdomen healed readily except for a portion on the left side where a sinus persisted, during the 2nd, 3rd and 4th weeks after operation, large quantities of creamy yellow pus drained from this wound. During that time there were nausea and upper abdominal pain made worse by eating, so that for a considerable period the patient was maintained on glucose given subcutaneously. During the last 2 weeks of life the amount of drainage from the operative wound subsided.

Throughout the postoperative course and, indeed, before operation the breathing was rapid somewhat labored and wheezing in type. By October 28, however, the patient seemed better in almost every way and the breathing was easier and quieter. On November 2 she was allowed up in a chair for a short period. On November 3, after she had been up about 30 minutes and was ready to return to bed she developed an acute attack of shortness of breath and quickly became comatose, pulseless and cyanotic. She rapidly failed and died within a few minutes.

Autopsy. At post-mortem examination no evidence of residual tumor was found in the pancreas. The liver was studded with many firm white, glistening, well demarcated nodules varying from 2 to 3 cm in diameter. The tumor replaced one third to half the liver substance. Histologic examination of the tumor tissue previously removed from the pancreas and liver at operation, and of that obtained from the liver at autopsy, showed the growth to be an islet-cell carcinoma of mixed type. Beta cells were demonstrated in the primary tumor but not in the metastatic lesions. Microscopic examination of the pituitary gland revealed marked basophilism. In addition to these findings, autopsy disclosed extensive thrombophlebitis of the right brachial, right axillary, right subclavian and right internal jugular veins, with complete occlusion of these vessels. There was thrombosis of the superior vena cava, with partial organization and occlusion. The immediate cause of death was pulmonary embolism, there were emboli in most of the secondary ramifications of the pulmonary artery. There were recent and old infarcts in the lower lobe of the right lung. (Detailed autopsy findings in this case, together with photomicrographs, appear in the article by Gray.)

Attempts in the laboratory of the New England Deaconess Hospital to determine the insulin content both of the primary tumor and of the nodules were unsuccessful from a quantitative standpoint probably because of unfamiliarity with the technique. A moderate lowering of the blood sugar was obtained, however, in a rabbit following the injection of an extract of liver nodules.

CASE 4 * B M, a 29-year-old housewife, was seen in the Out Patient Department of the Massachusetts General Hospital on August 14, 1940, and was admitted as an inpatient on September 12. She had been well up until December, 1937, when she began to experience attacks of weakness, dizziness, faintness and sweating and a feeling as if her mind were "paralyzed." At 11 00 a.m. on December 24, while at work at her sewing machine, she began to perspire profusely, her mind became blank and she fainted, unconsciousness lasted 17 hours. After this episode she gave up her job and remained at home for 5 months. She then resumed work, but after 4 or 5 weeks had another fainting spell while at work, on this occasion she was unconscious for 18 hours. Following another attack 2 days later, she was admitted to a hospital, where the blood sugar was found to be only 35 mg per 100 cc and roentgenograms of the skull were said to show no sign of tumor. She was placed on a special diet but found that to keep comfortable she always had to eat more than prescribed, and she had adopted a regime of eating between meals and at bedtime, in addition to the regular three meals. She had gained 40 pounds in weight in 2½ years. Although with such treatment she felt better and gained weight and strength and the attacks of syncope became milder, they seemed to occur almost as frequently as before (three or four times a month)—more frequently at the time of the menstrual period. The patient stated that during attacks she seemed unable to complete an action already started. The attacks were always relieved or aborted by food or glucose, and later the patient could recall nothing regarding the attack and chills and a "frozen feeling" were often present for some time.

A review of the past history showed no important illnesses, the patient remembered only measles and influenza in childhood. The family history was irrelevant except that two paternal aunts had died of cancer. The patient had been married for five years and had one child 3 years old.

Physical examination showed no significant abnormalities. The upper teeth were replaced by a satisfactory denture. The blood pressure was 118/85. The body weight was 124 pounds (56.5 kg) and the height 61½ inches (156 cm).

On August 14, 17 and 21 the fasting blood-sugar values were 38, 35 and 41 mg per 100 cc, respectively, and on September 13, 14, 27 and 30, they were 26, 30, 25 and 40 mg, respectively. Examination of the blood revealed a red-cell count of 4,940,000, with a hemoglobin of 90 per cent, and a white-cell count of 10,500, with a normal differential. The urine contained no albumin, sugar, bile or diacetic acid, and the sediment was normal. A blood Wassermann test was negative. The serum chloride was 99.6 and 108.1 milliequiv per liter on two occasions. The blood cholesterol was 144 mg, the serum nonprotein nitrogen 24 mg, and the serum protein 7.0 gm per 100 cc. The basal metabolic rate was -6 per cent. Roentgenograms of the gastrointestinal tract, chest and skull were negative.

On October 7 exploratory laparotomy was carried out through a wide transverse incision under nitrous oxide, oxygen and ether anesthesia. Considerable difficulty was experienced in locating a tumor, and even more trouble in removing it. It was finally found in and removed from the substance of the head of the pancreas, after removal, the tumor was found to have been directly over the beginning of the portal vein, which was not damaged during the operation. The tumor was definitely encapsulated and was soft, friable and purplish. During removal it was broken up into small fragments, the total weight was 750 mg. Assay showed a normal insulin content (3 units per gram). Histologically the tumor was an islet-cell adenoma.

The postoperative course was uneventful. The fasting blood sugar, which on the morning of October 8 was 155 mg per 100 cc, was 127 mg on October 9 and 93 mg on October 11. Following this the blood sugar stabilized at an entirely normal level and continued so until discharge on October 28.

The patient was seen in the Out Patient Department of the Massachusetts General Hospital on December 20, about 2½ months after operation. She had had no spells of weakness or fainting, although the appetite continued to be extraordinarily good. At this visit a blood-sugar determination about 12 hours after a meal was 67 mg per 100 cc, another determination, made 2 hours later and still in the fasting state, was 76 mg per 100 cc. At a visit on July 2, 1941, the

blood sugar 4 hours after eating a sandwich and milk was 97 mg per 100 cc. The patient had continued to feel entirely well and weighed 118 pounds. She was last seen on January 3, 1944, when the fasting blood sugar was 102 mg per 100 cc. In a letter dated April 26, 1946, she stated that she was doing all the housework for her family of five and that her appetite, weight and energy were normal.

CASE 5 E R, a 32-year-old bartender and taxi driver, had been admitted to a hospital on October 1, 1940, with the complaint that for a year he had experienced attacks of twitching of the face and neck, staggering in gait, weakness, dizziness and sleepiness, all relieved by food. Blood-sugar studies had shown extremely low values, and the diagnosis of probable islet-cell tumor was made. At operation on October 15 no tumor could be felt in the pancreas. The blood-sugar values continued to be low, and attacks persisted despite a high-protein, low-carbohydrate diet and phenobarbital daily.

Questioning on admission to the New England Deaconess Hospital on October 23, 1941, revealed that the symptoms had included the following: drowsiness leading to unconsciousness, weakness, sweating, rapid heart action, trembling and nervousness, numbness especially about the lips, inability to concentrate or to think clearly, staggering gait as that of a drunken man, twitching of the hands and face, peevishness, aggressiveness and blurring of vision. The first symptom usually noted was drowsiness. Attacks were definitely brought on more easily by exercise and by prolonged abstinence from food, food gave almost immediate relief. The patient first noticed his trouble because of difficulty at times in tying his tie. As a bartender he got along fairly well, because he could usually forestall attacks by taking food, but even so, at times he confused orders. Once while a taxi driver, he pulled his car up to the curb, got out and walked aimlessly for 5 blocks before a friend saw that something was wrong and took care of him, afterward, the patient did not recall the incident.

Physical examination showed no abnormalities. The patient seemed well developed and well nourished, the blood pressure was 104/70. The body weight was 166½ pounds (75.8 kg). Examination of the ocular fundi gave normal findings. Examination of the blood revealed a red-cell count of 5,070,000, with a hemoglobin of 17.7 gm per 100 cc, and a white-cell count of 10,650, with a normal differential. The urine contained no albumin, sugar, bile or diacetic acid, and examination of the sediment was negative. The serum protein was 6.4 gm and the nonprotein nitrogen 30 mg per 100 cc, and the serum chloride 97.3 milliequiv per liter. Roentgenograms of the skull, chest and gastrointestinal tract were negative. An electrocardiogram was normal.

At exploratory laparotomy on October 30 a completely encapsulated, soft tumor measuring 1.5 by 1.5 by 1.7 cm was removed from the pancreas. The tumor was a mottled red-gray in color. On microscopic examination it proved to be an adenoma of insular origin, consisting chiefly of beta cells, with scattered foci of ductal epithelium. Under sterile conditions Dr. J. Herbert Waite transplanted a small section of the tumor into the anterior chamber of the eye of a normal rabbit, the tumor failed to develop, however, and no signs of excessive insulin activity were evident from periodic tests of the rabbit's blood sugar.

Following operation the patient developed bronchopneumonia at both lung bases, particularly the left. Consequently he was uncomfortable during the first several days after operation, but gradually improved and left the hospital on December 1 in good condition. From his home physician it was learned that as late as May, 1946, he had continued to feel well and had had no attacks suggesting hypoglycemia.

CASE 6 S F, a 45-year-old farmer, was admitted to the New England Deaconess Hospital on November 8, 1941. He had felt well until 2 years previously, when he began to notice dizziness brought on particularly by exercise and was relieved by eating. Symptoms gradually increased to include weakness, fatigue and at times a change in temperament, irritability and a feeling of mental confusion. Various types of medical treatment had proved ineffective. The first indication of difficulty had occurred in the spring of 1938 while the patient was plowing corn. He noticed increasing difficulty and finally, when he stopped and let go of the reins, which had been partly supporting him, he felt dizzy and sank to

*This case was reported in 1941.⁵ Permission to include the patient in the present series was given by the Executive Committee of the Massachusetts General Hospital.

ground. When he finally got to the house and obtained relief, he felt relieved at once. This episode was the beginning of a long series of similar experiences. He soon adopted a schedule of taking orange juice or other food as soon as he awoke in the morning, before starting work. During the last several months he had had to give up most of the work about the farm because of the danger of hypoglycemic attacks. He regularly between meals and carried sugar in his pocket at all times. When attempts were made to arouse him from hypoglycemic stupor, he was occasionally simply confused and co-operated with difficulty, at other times he was pugnacious.

The family and past histories, except as already stated, are irrelevant.

Physical examination showed a well developed and well nourished man. The body weight was 208 pounds (94.5 kg). The heart, lungs and abdomen were normal, and the blood pressure was 110/70.

Examination of the blood showed a red-cell count of 3,200,000, with a hemoglobin of 15 mg per 100 cc, and a white-cell count of 9,600, with a normal differential. The urine contained only a slight trace of albumin and no sugar, and no diacetic acid; examination of the sediment was essentially negative. The blood sugar on November 10 was 41 mg per 100 cc. Subsequent values were uniformly at a low level, usually below 50 mg per 100 cc.

Operation was carried out on November 18 under nitrous oxide, oxygen and ether anesthesia. A long transverse incision was made across both rectus muscles. Exposure of the pancreas was quite difficult. The capsule was incised along the lower margin, and the pancreas lifted from its bed so that it could be carefully palpated between the fingers from the tip of the tail to the junction of the superior mesenteric and splenic veins. The free margin of the duodenum was then mobilized so that the head of the pancreas could be palpated between the fingers, the exploration being carried up to the point at which the pancreas had been explored from the other approach. Throughout this procedure nothing abnormal was seen or felt except that at the free margin of the head in the duodenal loop, there was a small, firm area about 1 cm in diameter within the pancreatic tissue. Although this area did not seem unusual, in the absence of any other abnormality, it seemed necessary to explore it further. This proved difficult, because of the extreme vascularity of the region. By blunt dissection a deep, purplish, encapsulated tumor about 1 cm in its greatest diameter was removed in one piece. Histologic examination showed an adenoma of the islet cells, with hyalinized stroma.

The postoperative course was uneventful. No further hypoglycemic attacks were experienced, and the blood-sugar values were within the normal range. The patient continued to be well. On August 4, 1946 (almost 5 years after operation), the patient stated in a letter that he had been in excellent health and had had no further difficulty of the sort experienced prior to the operation.

DISCUSSION

The 6 cases reported above are instructive in that they illustrate the various problems encountered in the diagnosis and treatment of patients with hyperinsulinism. Of especial interest are the patients in Cases 1 and 5, in whom no tumor had been found at a previous operation elsewhere, and the patient in Case 3, who was found to have a malignant tumor with metastases in the liver.

Symptomatology

Although the symptoms experienced by the patients were those common to reactions due to an overdose of insulin, in general they lacked the acute nature encountered following unmodified insulin. Although these patients often experienced sweating and nervousness, the symptoms were usually increasing mental confusion, bizarre behavior and drowsiness that finally passed into total uncon-

sciousness, with or without convulsions. Such symptoms developed if food was withheld for more than a few hours, and an overnight fast invariably resulted in a blood-sugar level well below normal and usually below 50 mg per 100 cc. In all cases physical exercise depressed the blood-sugar level still further and increased and hastened the onset of symptoms. Food or glucose gave prompt relief.

Diagnosis

Our experience with these and with other patients in whom the possibility of an islet-cell tumor has been raised is in agreement with that of Whipple³ and leads to the belief that when marked hypoglycemia with blood-sugar values below 50 mg per 100 cc regularly develops on fasting and is relieved by food, the presence of an islet-cell tumor must be assumed until proved otherwise, provided that by careful study extrapancreatic causes for the hypoglycemia have been excluded. These include diseases of the liver affecting glycogen storage and conditions associated with hypofunctioning of the adrenal cortex, the anterior lobe of the pituitary gland and the thyroid gland. Since conclusive evidence is lacking that the post-prandial hypoglycemia sometimes described in patients suffering from chronic fatigue⁶ is due to excessive nervous stimulation of islet tissue, the term "hypoglycemia" rather than "hyperinsulinism" is to be preferred for this condition.

No elaborate diagnostic procedures are necessary. The characteristic symptoms associated with well marked hypoglycemia brought on by fasting, increased by physical exertion and relieved by food are the important features. As an aid in the diagnosis, the glucose-tolerance test is of value only if carried out for a sufficient length of time — that is for four to six hours. Characteristically, the fasting blood sugar starts at a low level — usually below 50 and frequently below 40 mg per 100 cc. Following the administration of glucose, the rise in the blood sugar may be within normal limits or the curve may be diabetic in type. Conn and Conn⁷ suggest that the type of curve depends on the amount of carbohydrate in the diet of the preceding few days, diets high in carbohydrate increase and those low in carbohydrate reduce sugar tolerance. The glucose-tolerance curve up to the third hour, therefore, may be essentially normal or mildly diabetic in type except for the initial value. After three hours, however, the blood sugar usually falls sharply to a low level (in 5 of the 6 cases reported above to approximately 40 mg per 100 cc) and in the fourth, fifth and sixth hours shows no tendency to rise spontaneously (Table 2). This last fact is significant in normal persons one often obtains a hypoglycemic phase in the glucose-tolerance test but, presumably owing to the compensatory secretion of adrenaline, there is a spontaneous return to normal values. Such a return does not occur in

CASE 4 * B M, a 29-year-old housewife, was seen in the Out Patient Department of the Massachusetts General Hospital on August 14, 1940, and was admitted as an inpatient on September 12. She had been well up until December, 1937, when she began to experience attacks of weakness, dizziness, faintness and sweating and a feeling as if her mind were "paralyzed." At 11 00 a m on December 24, while at work at her sewing machine, she began to perspire profusely, her mind became blank and she fainted, unconsciousness lasted 17 hours. After this episode she gave up her job and remained at home for 5 months. She then resumed work, but after 4 or 5 weeks had another fainting spell while at work, on this occasion she was unconscious for 18 hours. Following another attack 2 days later, she was admitted to a hospital, where the blood sugar was found to be only 35 mg per 100 cc and roentgenograms of the skull were said to show no sign of tumor. She was placed on a special diet but found that to keep comfortable she always had to eat more than prescribed, and she had adopted a regime of eating between meals and at bedtime, in addition to the regular three meals. She had gained 40 pounds in weight in 2½ years. Although with such treatment she felt better and gained weight and strength and the attacks of syncope became milder, they seemed to occur almost as frequently as before (three or four times a month)—more frequently at the time of the menstrual period. The patient stated that during attacks she seemed unable to complete an action already started. The attacks were always relieved or aborted by food or glucose, and later the patient could recall nothing regarding the attack and chills and a "frozen feeling" were often present for some time.

A review of the past history showed no important illnesses, the patient remembered only measles and influenza in childhood. The family history was irrelevant except that two paternal aunts had died of cancer. The patient had been married for five years and had one child 3 years old.

Physical examination showed no significant abnormalities. The upper teeth were replaced by a satisfactory denture. The blood pressure was 118/85. The body weight was 124 pounds (56.5 kg) and the height 61½ inches (156 cm).

On August 14, 17 and 21 the fasting blood-sugar values were 38, 35 and 41 mg per 100 cc, respectively, and on September 13, 14, 27 and 30, they were 26, 30, 25 and 40 mg, respectively. Examination of the blood revealed a red-cell count of 4,940,000, with a hemoglobin of 90 per cent, and a white-cell count of 10,500, with a normal differential. The urine contained no albumin, sugar, bile or diacetic acid, and the sediment was normal. A blood Wassermann test was negative. The serum chloride was 99.6 and 108.1 milliequiv per liter on two occasions. The blood cholesterol was 144 mg, the serum nonprotein nitrogen 24 mg, and the serum protein 7.0 gm per 100 cc. The basal metabolic rate was -6 per cent. Roentgenograms of the gastrointestinal tract, chest and skull were negative.

On October 7 exploratory laparotomy was carried out through a wide transverse incision under nitrous oxide, oxygen and ether anesthesia. Considerable difficulty was experienced in locating a tumor, and even more trouble in removing it. It was finally found in and removed from the substance of the head of the pancreas, after removal, the tumor was found to have been directly over the beginning of the portal vein, which was not damaged during the operation. The tumor was definitely encapsulated and was soft, friable and purplish. During removal it was broken up into small fragments, the total weight was 750 mg. Assay showed a normal insulin content (3 units per gram). Histologically the tumor was an islet-cell adenoma.

The postoperative course was uneventful. The fasting blood sugar, which on the morning of October 8 was 155 mg per 100 cc, was 127 mg on October 9 and 93 mg on October 11. Following this the blood sugar stabilized at an entirely normal level and continued so until discharge on October 28.

The patient was seen in the Out Patient Department of the Massachusetts General Hospital on December 20, about 2½ months after operation. She had had no spells of weakness or fainting, although the appetite continued to be extraordinarily good. At this visit a blood-sugar determination about 12 hours after a meal was 67 mg per 100 cc, another determination, made 2 hours later and still in the fasting state, was 76 mg per 100 cc. At a visit on July 2, 1941, the

blood sugar 4 hours after eating a sandwich and milk was 97 mg per 100 cc. The patient had continued to feel entirely well and weighed 118 pounds. She was last seen on January 8, 1944, when the fasting blood sugar was 102 mg per 100 cc. In a letter dated April 26, 1946, she stated that she was doing all the housework for her family of five and that her appetite, weight and energy were normal.

CASE 5 E R, a 32-year-old bartender and taxi driver had been admitted to a hospital on October 1, 1940, with the complaint that for a year he had experienced attacks of twitching of the face and neck, staggering in gait, weakness, dizziness and sleepiness, all relieved by food. Blood sugar studies had shown extremely low values, and the diagnosis of probable islet-cell tumor was made. At operation on October 15 no tumor could be felt in the pancreas. The blood-sugar values continued to be low, and attacks persisted despite a high-protein, low-carbohydrate diet and phenobarbital daily.

Questioning on admission to the New England Deaconess Hospital on October 23, 1941, revealed that the symptoms had included the following: drowsiness leading to unconsciousness, weakness, sweating, rapid heart action, trembling and nervousness, numbness especially about the lips, inability to concentrate or to think clearly, staggering gait as that of a drunken man, twitching of the hands and face, pugnaciousness, aggressiveness and blurring of vision. The first symptom usually noted was drowsiness. Attacks were definitely brought on more easily by exercise and by prolonged abstinence from food, food gave almost immediate relief. The patient first noticed his trouble because of difficulty at times in tying his tie. As a bartender he got along fairly well, but because he could usually forestall attacks by taking food, but even so, at times he confused orders. Once while a taxi driver, he pulled his car up to the curb, got out and walked aimlessly for 5 blocks before a friend saw that something was wrong and took care of him, afterward, the patient did not recall the incident.

Physical examination showed no abnormalities. The patient seemed well developed and well nourished, the blood pressure was 104/70. The body weight was 166½ pounds (75.8 kg). Examination of the ocular fundi gave normal findings. Examination of the blood revealed a red-cell count of 5,070,000, with a hemoglobin of 17.7 gm per 100 cc, and a white-cell count of 10,650, with a normal differential. The urine contained no albumin, sugar, bile or diacetic acid, and examination of the sediment was negative. The serum protein was 6.4 gm and the nonprotein nitrogen 30 mg per 100 cc, and the serum chloride 97.3 milliequiv per liter. Roentgenograms of the skull, chest and gastrointestinal tract were negative. An electrocardiogram was normal.

At exploratory laparotomy on October 30 a completely encapsulated, soft tumor measuring 1.5 by 1.5 by 1.7 cm was removed from the pancreas. The tumor was a mottled red-gray in color. On microscopic examination it proved to be an adenoma of insular origin, consisting chiefly of beta cells, with scattered foci of ductal epithelium. Under sterile conditions Dr J Herbert Waite transplanted a small section of the tumor into the anterior chamber of the eye of a normal rabbit, the tumor failed to develop, however, and no signs of excessive insulin activity were evident from periodic tests of the rabbit's blood sugar.

Following operation the patient developed bronchopneumonia at both lung bases, particularly the left. hyperinsulinism, probably because of the continuous secretion of insulin by the islet-cell tumor

The glucose-tolerance curve in patients with hyperinsulinism differs from that described by Portis⁶ in patients with hypoglycemia associated with vagotonia and fatigue in the following particulars in the latter condition the fasting blood sugar, although perhaps lower than the average normal, is not depressed to the extent seen in hyperinsulinism, the

In 5 of the patients the tumor was an adenoma, more or less encapsulated, composed chiefly of beta cells. In 1 a carcinoma of mixed-cell type was present, with multiple metastatic nodules in the liver.

The tumors in the 6 patients were uniformly small nodules, varying from about 1 to 2 cm in diameter, although in the patient with carcinoma several of the nodules in the liver were larger. Although most of the reported islet-cell tumors were small, average

†On this date 80 gm of glucose was given

‡Tests performed at Duval County Hospital, Jacksonville, Florida

curve tends to be flat, and the lowest blood sugar usually occurs two, three or four hours after the administration of glucose, and there is a tendency to return to normal without the administration of food or glucose

Various secondary tests may be carried out, including blood-sugar studies following the giving of epinephrine, pituitary extract, ergotamine and insulin. One would expect the blood-sugar-raising effect of epinephrine and pituitary extract to be less and the blood-sugar-lowering effect of insulin to be greater than those in normal persons studied under the same conditions. This is true in general, but our experience has been that although the results obtained are interesting, they are apt to be variable and do not contribute significantly to the diagnosis. Table 3 shows the values obtained in such studies with our patients.

Location, Type and Size of Tumors

Although islet-cell tumors are said to occur most frequently in the tail of the pancreas, in these 6 cases the tumor was found in the head in 4 cases and once each in the body and tail of the pancreas

ing about 1.5 cm in diameter, some were quite large. The one reported by Brunswick,⁸ which was 13 by 10 cm, and in its greatest diameter, 15 cm, weighed 673 gm. In the case reported by O'Leary and Womack⁹ the growth was likewise quite large, measuring 11 by 9 by 9 cm and weighing 500 gm. The tumor in Brunswick's case was of especial interest, since because of a previous exploration it was known to have increased in size from about 7 to 15 cm in diameter over a period of four months, nevertheless, and despite the fact that the tumor appeared malignant histologically, there was no gross evidence of metastasis at the time of the second operation.

Surgical Treatment

Once the diagnosis of a probable islet-cell tumor has been made, exploration should be urged, not only for symptomatic relief but also because of the possible danger of damage to the central nervous system produced by repeated attacks of prolonged hypoglycemia and because of the possibility of malignant degeneration of a tumor originally benign.

d with well marked hypoglycemia (blood-sugar concentrations usually below 50 mg per 100 cc) brought on by fasting, increased by physical exertion and relieved by food. The glucose-tolerance test is of aid in diagnosis only if carried out for a sufficient length of time—that is for four to six hours—to allow the blood sugar to fall to an abnormally low level.

Because of the danger of damage to the central nervous system by repeated attacks of prolonged hypoglycemia and because of the possibility of malignant degeneration of a tumor initially benign, early exploratory operation is urged in patients in whom the diagnosis of islet-cell tumor with hyperinsulinism has been made.

We are indebted to Drs. Joseph F. Ross, H. A. Cochrane, Benjamin Burley, Arthur LaSalle, Karl Hanson and James A. McCollough for permission to observe the patients whose cases are reported in this paper.

UNRECOGNIZED VESICAL-NECK OBSTRUCTION IN WOMEN*

CHARLES E. JACOBSON, JR., M.D.†

HARTFORD, CONNECTICUT

MOST urologists are aware of the fact that vesical-neck obstruction in women exists, but not all, I believe, are aware of the fact that it is not an infrequent entity. Although no statistics are available regarding its incidence the condition undoubtedly occurs oftener than is ordinarily appreciated, and I have seen 4 advanced cases in the last two years. Caulk¹ (1921), Nesbit² (1933), Fite³ (1934), Thompson⁴ (1935) and van Houtum⁵ (1935) reported 1 or more cases, and Mirabile⁶ presented a case in 1942. The principal reason for the presentation of the following cases is not only to call attention to this condition again but also to urge that it be recognized early and that its treatment be instituted early enough to avoid the late sequelae of such obstruction. The word "unrecognized" is used to indicate that this condition may easily be overlooked during the routine urologic examination of the patient.

The following brief summaries illustrate the important findings in 3 cases of vesical-neck obstruction in women.

CASE 1 (H. H. 471-447) L. S., a 71-year-old married woman, had had severe urgency, dysuria, frequency and nocturia as often as 10 to 15 times of several months' duration. Prior to this, and for as long as she could remember, she had had difficulty starting urination and had had to get up several times nightly. A stone had been removed from the lower right ureter 4 months previously, with no improvement in the symptoms.

*Presented at a meeting of the New England Section of the American Urological Association, Boston, April 4, 1946.

†Attending urologist, Manchester Memorial Hospital, Manchester, Connecticut, and Veterans Hospital, Rocky Hill, Connecticut; assistant attending urologist, McCook Memorial Hospital, Hartford, Connecticut.

Urinalysis revealed moderate pyuria and on urinary culture *Aerobacter aerogenes* was grown. On several determinations the residual urine ranged from 600 to 700 cc. Cystoscopy disclosed a large, moderately trabeculated bladder, with an irregular type contracture of the vesical neck and two diverticulae.

FIGURE 1 Case 1. Cystogram showing a large atonic bladder, with two diverticulae.

in the right base of the bladder. A cystogram showed a large, atonic appearing bladder, with two diverticulae (Fig. 1). A urogram revealed mild pyelectasis and a hydronephrosis on the right. The left kidney and ureter appeared normal.

A partial sphincterectomy was performed. 2 gm. of tissue from the posterior vesical lip being removed. Pathologically the tissue consisted of smooth muscle and transitional epithelium.

In reviewing the literature before 1944, Frantz,¹⁰ working with Whipple, found a total of 149 cases of islet-cell tumor with hypoglycemia, including those removed at operation and those found at autopsy, 106 cases were shown to be benign, 28 were questionably malignant and 15 were proved malignant since there were metastases in adjacent organs

Microscopic examination of tumor tissue from the 5 patients with adenoma showed the capsule of the tumor to be incomplete in each of the 4 cases in which enough tissue was available for satisfactory examination (Table 1) In 1 of the 5 cases, questionable blood-vessel invasion was noted This is in keeping with the experience of Frantz,¹¹ who stressed the fact that great difficulty is often encountered in the histologic differentiation of malignant and benign islet-cell tumors Usually, the tumors show encapsulation of varying degrees of completeness, but in some cases there is no capsule and tumor cells are found in the blood vessels Certain patients from whom tumors of questionable type were removed, however, have remained alive many months after operation¹² Frantz¹⁰ states that in the group of questionable tumors the suspicion of the pathologist, not that of the surgeon, has yet to be confirmed in a single case by follow-up data The suggestion is made that these tumors are analogous to the so-called "adenoma malignum" type of carcinoma of the thyroid gland, which is slow growing and late to metastasize At any rate, there is sufficient basis for urging surgical exploration in any patient in whom the diagnosis of probable islet-cell tumor has been made

Experience has shown that if, despite careful search, no tumor is found at operation, the possibility is nevertheless great that a small tumor has been overlooked In most reported cases in which a portion of the pancreas has been resected and no evidence of tumor or adenomatosis found, little or no clinical improvement followed the operation¹⁰ It is well, therefore, to be cautious in making the diagnosis of functional hyperinsulinism—that is, hypoglycemia of chronic, recurrent nature due to hyperfunctioning of islet cells without the presence of a tumor The term "hyperinsulinism" should be reserved for that condition in which excessive secretion of insulin occurs because of overactivity of islet tissue

The approach to the pancreas through a long, curving transverse incision just above the umbilicus and through both rectus muscles has proved satisfactory In the exploration one cannot overemphasize the value of freeing the pancreas thoroughly so that it may be palpated throughout its extent from the tip of the tail to the head, and so that it may be visualized over as large a part of its course as possible This means that infinite pains and patience are required and that at times the operation will be long Of our 6 patients, 2 had

been operated on previously by competent surgeons and yet the tumor was overlooked Palpation must be sufficiently thorough and delicate to disclose a tiny nodule embedded within the substance of the pancreas and not visible from either surface If one is convinced of the diagnosis prior to operation, the exploration should be carried to the limit in an attempt to demonstrate a tumor Even though one nodule has been found, the exploration should be continued because of the relatively high incidence of multiple tumors¹⁰⁻¹² In Maxeiner's¹³ case clinical recovery from attacks of hypoglycemic seizures followed the removal of 75 per cent of the pancreas, examination of the resected portion showed eight small islet-cell tumors If no tumor is found after careful exploration, decision must be made regarding resection of a portion of the pancreas The consensus appears to be that resection under these circumstances should be of radical nature^{14, 15}

It is surprising how well patients withstand manipulation of the pancreas and removal of the tumors With the exception of the patient who had a carcinoma with metastases, all our patients did well postoperatively It is true that one patient developed bronchopneumonia, but the illness was not prolonged and he left the hospital in good condition a month after operation

SUMMARY

Six cases of islet-cell tumor of the pancreas with hyperinsulinism, verified at operation, are reported In 5 cases, removal of a single adenoma resulted in the relief of symptoms that has persisted more than four to seven years after operation In 1 case death followed seven weeks after operation, which disclosed an islet-cell carcinoma, with multiple metastases in the liver

Of the 5 patients with benign adenoma 3 were women and 2 men The ages at the time of operation ranged from sixteen to forty-nine years The period from the onset of symptoms varied from two to eight years In 4 cases the tumor was in the head and in 1 in the body of the pancreas Two of these patients had been operated on previously without the discovery of a tumor

The patient with carcinoma was a woman of fifty-nine years at the time of operation, with symptoms of four years' duration In this case the primary tumor was in the tail of the pancreas

Microscopic examination of tumor tissue from the 5 patients with adenoma showed the capsule of the tumor to be incomplete in each of 4 cases in which there was enough tissue available for satisfactory examination In 1 case questionable blood-vessel invasion was noted

In the 4 cases in which assays were carried out, the insulin content ranged from 3 to over 100 units per gram of tumor tissue

The important features in the diagnosis of islet-cell tumor are the characteristic symptoms associ-

is disconcerting to note that the amount of fibrous tissue found at autopsy in the vesical neck of a series of normal women was similar to that observed in a series of cases of vesical-neck obstruction subjected to transurethral surgery. Furthermore, it seems reasonable to assume that if chronic infection and its accompanying cicatrization were factors the obstruction would be seen much oftener than it is. According to Thompson⁴ it seems almost certain that something other than fibrosis is responsible for the retention of urine in these cases. The theory of imbalance between the sympathetic and parasympathetic innervations of the bladder has also been questioned of late as a result of recent experimental work that has tended to minimize the importance of the sympathetic innervation. In experimental studies the sympathetic innervation was completely excised, with little, if any, alteration in the animal's ability to void. In keeping with this change in the concept of the physiology of micturition the theory of imbalance has received less support.

The presence and the significance of the urethral glands—the so-called “female prostate”—in the development of chronic vesical-neck obstruction has been the subject of much discussion. There is no question that such glands do exist and, when enlarged, actually cause mechanical obstruction or, as is more frequently observed, influence the chronicity of the urethritis and contribute to the resulting cicatrization of the urethra and vesical neck. Although the glands are undoubtedly involved in some cases it is my impression that their role is minor. Questionable glands were present in only 1 of my 4 cases.

The symptoms of chronic vesical-neck obstruction in women are similar to those in men. Urination may be difficult to initiate, or urgency to the point of incontinence may be present. Dysuria, which is usually observed, may be associated with vesical tenesmus and strangury. Frequency and nocturia are usually marked and generally constitute the chief complaints. Recurring hematuria was present in 2 of the cases presented above. The symptoms are usually of long duration, 2 of the 3 patients complained that voiding had been abnormal all their lives. Chronic cystitis is the diagnosis usually made in these cases.

In addition to the general physical examination a careful neurologic and vaginal examination should be performed to exclude the presence of neurogenic vesical dysfunction and to rule out such complicating factors as cystocele, urethral diverticulum and urethral tumor.

The urologic examination should include a routine urinalysis, determination of the residual urine and a careful cystoscopic examination. A cystogram is helpful. Examination of the upper urinary tracts is sometimes quite revealing. Cystometry, although

interesting, was not particularly illuminating or helpful in my cases.

Urinalysis reveals a pyuria of greater or lesser extent, and urine culture yields the usual microorganisms found in lower urinary-tract infections. Microhematuria may also be present.

Determination of the residual urine is perhaps the most significant single test that is made. This is particularly true in cases in which the cystoscopic findings are minimal or inconclusive. If residual urine is present resection of the vesical neck is indicated.

The cystoscopic findings in the advanced cases are usually obvious. Marked trabeculation, cellulose formation, sacculation and diverticula may be present, and all suggest the presence of vesical-neck obstruction as they do in men. The vesical neck itself appears to be contracted and is usually pale, suggesting the presence of cicatrization; it is also rigid and relatively fixed in position. Median-bar formation may be prominent or, as is most frequently observed, an iris-diaphragm type of contracture is present in which the internal vesical orifice actually diminishes in size as the bladder is distended. Cystoscopic visualization of the vesical neck is best performed with a direct-vision cystoscope or, if this is not available, with a for-oblique lens system. The use of a retrograde lens is helpful in that the obstruction may occasionally be more readily recognized from the vesical rather than a urethral aspect.

Early vesical-neck obstruction is difficult to recognize and usually escapes detection. The cystoscopic findings are minimal and at most may consist only of early trabeculation. The vesical neck may or may not appear to be contracted, and there is no residual urine. The most significant finding in my experience is the presence of rigidity in the vesical neck that is discernible when the bladder is completely empty and flaccid. A suspicion of early vesical-neck obstruction is probably the best assistance in its diagnosis.

The ideal treatment in cases of contracted vesical neck consists in removing all the obstructing tissue or in resecting the entire vesical neck or so-called “internal vesical sphincter.” Although this procedure is ideal it is not always necessary, and resection of the posterior vesical lip or median bar is frequently all that is required. Sphincterotomy or incision of the posterior vesical lip, although helpful, is usually of only temporary benefit. Urethral dilatation is the least desirable form of treatment. Following the resection an indwelling catheter is left in for forty-eight to seventy-two hours, after which frequent catheterization and vesical lavage may be necessary to facilitate the return of vesical tone and the elimination of residual urine. Eradication of the urinary-tract infection may be helped with chemotherapy.

The residual urine gradually diminished, and within 2 weeks all symptoms had subsided.

CASE 2 (H H 484-675) B W, a 74-year-old spinster, had been troubled with urgency, dysuria, recurring hematuria, frequency and nocturia of 4 to 10 times as long as she could remember. Urologic examination 3 years previously had revealed "chronic alkaline-encrusted cystitis," and vesical lavage had been advised. Cystoscopy at that time had revealed trabeculation and cellules.

Urinalysis showed grossly turbid, hemorrhagic urine containing *Proteus ammoniae*. The residual urine varied between 90 and 100 cc. Cystoscopy disclosed a markedly trabeculated

A single section of tissue was resected at the midpoint of the posterior vesical neck, followed by dilatation of the urethra. On pathological examination the fragment of the vesical neck consisted of thickened and edematous mucosa.

FIGURE 2 Case 2 Cystogram showing a pyramidal trabeculated bladder, with many cellules

bladder, with many cellules and diffused cystitis. The bladder neck was rigid and contracted. A cystogram demonstrated a pyramidal, trabeculated bladder, with many cellules (Fig 2). Normal upper urinary tracts were seen on a urogram.

A total internal sphincterectomy was performed, 5 gm of tissue being removed from the entire circumference of the vesical neck. Pathological examination revealed tissue composed of smooth muscle and fibrous tissue, with a border lined with stratified squamous epithelium.

Within 6 weeks the residual urine had diminished, and the symptoms were markedly ameliorated.

CASE 3 (H H 528-588) A H, a 73-year-old married woman, complained of hematuria of 3 weeks' duration. Six years previously she had had hematuria, and complete urologic investigation had revealed only cicatricial urethritis. She had also suffered for several years with severe dysuria, mild stress incontinence, frequency and nocturia of 6 times.

On urinalysis moderate pyuria and gross hematuria were demonstrated. On culture *A. aerogenes* was grown. There was approximately 100 cc of residual urine. At cystoscopy the bladder was badly deformed, with multiple cellules and marked trabeculation and dilated ureteral orifices. The vesical neck was rigid and contracted. A moderate cystocele was present. A cystogram revealed a pyramidal bladder with marked trabeculation and multiple cellules in the apex of the pyramid (Fig 3). The base of the bladder was smooth, suggesting the presence of a cystocele. Bilateral ureteral reflux demonstrated a bilateral hydroureter. A urogram showed bilateral hydronephrosis.

FIGURE 3 Case 3 Cystogram showing a pyramidal bladder, with marked trabeculation and multiple cellules in the apex of the pyramid, as well as a cystocele and bilateral ureteral reflux and hydroureters.

with chronic inflammatory changes in the submucosa. Several small foci of epithelium present below the surface were slightly cystic and suggested cystitis cystica.

The hematuria subsided and the patient's symptoms improved greatly. Nocturia of 2 times persisted. The residual urine diminished to 10 cc.

The advanced ages of these patients and of another patient not reported indicate that in women this condition is usually present in the older age groups, as it is in men. Of the cases reported in the literature the greatest number were in this same age group. "Prostatism sans prostate" seems a particularly appropriate term to describe this group of cases.

The etiology of vesical-neck obstruction in the female is not definitely established. Perhaps the most popular theory is that the obstruction is due to a contracture of the vesical neck resulting from sclerosis or fibrosis at this site, the fibrosis being attributed to chronic low-grade inflammation of the urethra or to vaginal trauma. Some observers believe that the contracture is due to hypertrophy of the muscle fibers at the vesical neck and is not the result of cicatrization at this site. Another point of view is that the obstruction is fundamentally physiologic and due to dysectasia or achalasia—in other words, to a failure of the vesical neck to relax as the bladder contracts. This theory implies that the innervation of the bladder and vesical neck is at fault, and an imbalance between the sympathetic and the parasympathetic innervations is considered responsible.

In the light of present knowledge no one explanation is completely satisfactory. Although the theory of fibrosis of the vesical neck seems plausible enough,

ever pain and collapsed. She died on the operating table. An aneurysm of the left renal artery was discovered. Eiss,⁵ who reported 2 fatal cases of retroperitoneal hemorrhage in men, stated that the differential diagnosis in women must include the following: ectopic pregnancy, perforated gastric ulcer, appendicitis, and if trauma is a factor, a ruptured viscus. He believed that there must be prompt exploration to find the cause. When the hemorrhage is retroperitoneal the abdomen should be closed immediately and the shock treated. He stated that a careful search of the literature revealed only 7 cases similar to the 2 he reported. Lāwen⁶ also reported 2 fatal cases in men. One patient had a preoperative diagnosis of left perirenal hemorrhage, and a retroperitoneal operation was performed. Autopsy revealed a large left retroperitoneal hemorrhage from a perforation of the inferior vena cava at its junction with the left common iliac vein. There was a chronic inflammatory infiltration of the wall of the vein (phlebitis dissecans) and also an old thrombophlebitis, which he believed secondary to a chronic knee condition. The other patient had right renal colic, and the preoperative diagnosis was retroperitoneal tumor. Extraperitoneal operation revealed a cyst containing 1000 cc of old blood. The cyst wall was formed probably by organization of the peripheral parts of the hematoma. The kidney, as part of the wall, was removed. Seven weeks after operation the patient collapsed. A large cavity filled with blood, which was found after entry through the old incision, was emptied and packed. The patient finally died of pulmonary embolism. Post-mortem examination revealed sarcoma of the lumbodorsal fascia, with metastases scattered in various areas.

Halban⁷ believed that a retroperitoneal hemorrhage is nearly always perirenal at the start, that it may be secondary to tuberculosis or tumor of the kidney and that it may also occur spontaneously in nephritis and hemophilia. He stated that the bleeding caused by trauma, tuberculosis and tumor is of no special interest but that the spontaneous, essential hemorrhages, in spite of many observations, have not yet been fully explained.

The following case report is unique in two respects: it is the only case of retroperitoneal hemorrhage complicating pregnancy with recovery that has been reported, and describes for the first time a new entity causing dystocia.

CASE REPORT

B. F., a 38-year-old woman, had been married for 12 years. A child, weighing 6 pounds, 12 ounces, had been born 11 years previously; the pregnancy, delivery and convalescence had been normal. The past history revealed an appendectomy at the age of 26 but no serious medical illnesses. The menstrual history was normal. The patient's father and mother and three siblings were living and well, there was no history of the usual familial diseases. The last menstrual period had begun on February 2, 1945, and confinement was expected on November 24.

Physical examination was negative. On the first visit on June 5 the uterus, which was enlarged about two thirds the

way to the umbilicus, seemed slightly firmer than usual. The impression was gained that the uterus was slightly larger than the dates indicated, but the patient was not absolutely sure of the date of the last catamenia. The weight was 140 pounds. The blood pressure was 150/90, and the pulse 80. Examination of the blood revealed a red-cell count of 4,010,000, with a hemoglobin of 72 per cent (Sahl). The blood was of Group 0 and was Rh—. The blood Hinton reaction was negative.

The patient had an uneventful pregnancy. Vaginal examination on November 17, approximately a week before the expected date of confinement, revealed a cervix that was partly taken up and soft and slightly anterior to the usual position. It admitted a finger readily. The presenting part, however, was not definite. On December 1 the patient was admitted to the Cambridge Hospital because of moderate pain in the left side. Physical examination revealed slight tenderness along the course of the ureter, there was no costovertebral tenderness. The uterus was soft, and the fetus appeared to be slightly less than average size. The temperature was 99.2° F., and the pulse 92. A catheterized specimen of the urine was taken, the report of the sediment was equivocal—there were said to be 40 or 50 white cells per high-power field. An anteroposterior film revealed a fetus of a size consistent with an 8 months' pregnancy and in a left occipitoanterior position, the head was unusually high. Vaginal examination revealed a tender, moderately firm mass filling the posterior part of the pelvis and pushing the cervix up behind the symphysis. The diagnosis was probable fibroid of the lower segment of the uterus causing dystocia. Cesarean section was deemed advisable.

At operation on December 5 under continuous spinal anesthesia employing 6 mg. of pontocaine, the usual midline incision was made below the umbilicus and the abdomen was opened. A small amount of blood was found in the left side of the lower abdominal cavity. The bladder flap, which was somewhat soggy and thin, was stripped from the uterus, and a transverse incision was made in the lower segment. A female infant weighing 5 pounds, 6 ounces, was extracted. The uterus was brought out of the incision for examination of the abdomen. Whereas previous to the incision in the uterus, the examiner's hand had been passed around the uterus without palpating a fibroid, inspection revealed a large, firm, retroperitoneal hemorrhage that filled the whole true pelvis and extended well into the mesentery of the sigmoid, which was ribboned out over the hemorrhagic mass. The diagnosis was retroperitoneal hemorrhage in the true pelvis causing dystocia. It was decided that the best treatment was to leave the hemorrhagic area undisturbed. The placenta had been delivered while the character and extent of the mass were being investigated. The uterus was closed with No. 1 catgut in two layers. Five grams of sulfanilamide was placed under the bladder flap, which was overlapped with a fine suture. The abdomen was closed in layers, No. 1 chromic catgut being used for the peritoneum and fascia and silk for the skin.

There was no excessive bleeding from the incision or the uterus, and the postoperative condition was good. On December 6 the temperature was 100.6° F., and the pulse 106 to 150. Distention was slight. Rectal examination revealed that the mass could be readily felt and was still tender. Two days later the temperature varied from normal to 99.2° F. There was no distention. The general condition was good. On December 14, when the patient was allowed to sit up, the temperature still varied from normal to 99.2° F. Otherwise, the general condition was excellent. The patient was discharged on the 15th day.

Pelvic examination on February 23, 1946, revealed a slightly tender, firm mass—about 5 cm. in diameter—posterior to the cervix but not projecting far into the vagina. The hematoma was evidently being absorbed slowly. There was slight to moderate discomfort in the left lower abdomen. On May 20, when the patient still complained of vague back and lower abdominal discomfort, examination revealed slight tenderness behind the cervix, but the hematoma, which was smaller, was palpated with difficulty.

SUMMARY

Retroperitoneal hemorrhage complicating pregnancy is extremely rare but probably occurs more frequently than reports indicate. One type is characterized by severe abdominal pain and shock as a

SUMMARY

Three cases of chronic vesical-neck obstruction in women are presented in which resection of all or part of the vesical neck was performed with satisfactory relief of symptoms.

Attention is drawn to the facts that the condition is not infrequent and that dire consequences, in the form of dilatation of the upper urinary system, may ensue if treatment is not instituted early in the course of the disease.

A search for the presence of early vesical-neck obstruction in every case of chronic cystitis in women

is urged, so that this condition may be recognized and adequate treatment instituted.

RETROPERITONEAL HEMORRHAGE] COMPLICATING PREGNANCY*

Report of a Case

CORNELIUS T. O'CONNOR, M.D.,† AND JOSEPH J. BRADLEY, M.D.‡

BOSTON

IN 1918 Potocki¹ reported a case of retroperitoneal hemorrhage complicating pregnancy in which the patient, two and a half months' pregnant, experienced pain in the lower abdomen after intercourse. The pain extended gradually to the left side, with some degree of shock. Shortly after admission to the hospital the pain became severer and the shock deeper. The diagnosis was ruptured tubal pregnancy or pregnancy with an ovarian cyst with a twisted pedicle. Laparotomy performed immediately revealed an extensive retroperitoneal hemorrhage that did not involve the true pelvis but filled the mesocolon and the retroperitoneal areas in the region of the pancreas, left kidney and stomach. The patient died on the operating table. Autopsy did not disclose the bleeding vessel. It was concluded that a major vessel had perforated because 1200 to 1800 cc of blood was present retroperitoneally. The left kidney was found to be tuberculous, and a large hematoma surrounded the kidney. Potocki believed that the probable cause of the hemorrhage was a miliary aneurysm of the renal artery. His search of the literature failed to reveal any other case occurring in pregnancy, but disclosed similar cases in men, one of which was a spontaneous fatal hemorrhage from a psoas-muscle vessel. In another case severe pain developed in the left side of the abdomen, and a mass could be felt in the left renal region, the patient died on the operating table, and post-mortem examination revealed a large retroperitoneal hemorrhage, small abscesses in the kidney and stones. A third patient, who had syphilis, died of a cerebral accident, and autopsy disclosed a large retroperitoneal hemor-

rhage that was believed to have started from the renal artery, since there was a history of an old perirenal abscess. Potocki concluded that pregnancy did not predispose a patient to this condition and believed that in most cases the hemorrhage started from renal vessels.

Low,² in 1944, reported a fatal case in pregnancy. The patient, within two weeks of term, was admitted to a hospital several hours after being seized with violent pain originating in the left upper quadrant of the abdomen and extending to the back. The pain occurred after a bowel movement, and shock ensued shortly after its onset. A transfusion was given, and a classic cesarean section was performed. A moderate amount of blood-stained fluid was found in the abdomen, but the essential finding was a massive retroperitoneal hemorrhage extending from above the left brim of the true pelvis and behind the sigmoid, descending colon and splenic flexure, across the midline of the upper abdomen and apparently most marked in the region of the spleen and left kidney. The patient died seven hours after operation, in spite of another transfusion. Post-mortem examination revealed all the large arteries to be relatively thin walled, and the left ovarian artery to be particularly so, as well as dilated and tortuous and presenting some aneurysmal dilatation near its origin. Kenny,³ in 1945, reported a similar case in which the patient, who had pre-eclampsia and was at term, had pain and shock following intercourse. A retroperitoneal hemorrhage extending from the pelvic brim to the diaphragm was discovered. The source of the bleeding was not found at autopsy. Kenny believed that the source of the hemorrhage was the retroperitoneal capillaries.

Wilson⁴ delivered normally at full term a patient who twenty-six hours post partum experienced

the divergent results were due in some degree to the unreliability of the chemical methods available. Technical difficulties arising from the small amounts of material used, impurities in the framework of the tablets and errors arising from colorimetric analysis are a few of the factors that contributed to the unreliability of these reports.

The fall in blood pressure in anesthetized rabbits after intravenous administration of small amounts of nitroglycerin was utilized as a method of biologic assay for nitroglycerin deterioration by Edmunds and Roth¹⁵. On the basis of their findings they concluded that tablets not more than two years old had lost practically none of their strength but that older tablets had deteriorated to some extent.

Although the results of chemical and biologic assay methods when applied to the question of deterioration of nitroglycerin with age have not been conclusive, it is generally believed by pharmaceutical manufacturers and clinicians that nitroglycerin is not a stable preparation. Accordingly, current medical opinion, as expressed in leading textbooks of cardiology and general therapeutics, recommends that patients employing nitroglycerin for the treatment of angina pectoris discard old tablets and purchase fresh ones every three to six months.

MATERIAL AND METHODS

The clinical potency of readily soluble hypodermic tablets of nitroglycerin of varying age in doses of 0.6, 0.4, 0.3, and 0.1 mg (1/100, 1/150, 1/200 and 1/500 gr) were investigated. Fifteen different preparations were tested. Three were fresh tablets (less than two months old). Three others had been on the laboratory shelves in pasteboard pillboxes for periods ranging from three to five years. Five were obtained from the shelves of retail drugstores and pharmaceutical houses, where they had remained for four to eleven years, no special precautions against deterioration had been taken in packaging and storage. Three samples originally less than two months in age were kept in pasteboard pillboxes in an incubator at 37° C for three additional months to ascertain the effect of heat on their clinical effectiveness. The remaining sample consisted of fresh readily soluble hypodermic tablets (0.3 mg) that had been kept in a loosely fitting screw-cap vial and carried by 2 patients for four months close to the body in the same vest or trousers pocket used for carrying their clinical supply of nitroglycerin.

Five male patients with angina pectoris, who had demonstrated a moderate to marked response following sublingual administration of nitroglycerin, were selected for these studies. The patients had been followed in a special clinic at weekly intervals for periods ranging from six months to eleven years. The amount of exercise each patient could perform before developing an attack of angina pectoris, as demonstrated by the standardized exercise tolerance test, had been determined on many occasions ac-

cording to a method previously described¹⁶. The exercise, which consisted in mounting and descending a two-step staircase in a room maintained at a temperature of 45 to 50° F, was carried out approximately an hour after the patient had had a light breakfast and had rested for half an hour in the clinic. Only one test was attempted on any given day. The number of trips each patient could perform gave a measure of the exercise tolerance. During the period of study the patients were given only placebo medication except for nitroglycerin as needed in their everyday activities.

The exercise tolerance as determined on many occasions without medication was used as the control for the subject concerned. As a further check the exercise tolerance was measured two minutes after the sublingual administration of blank hypodermic tablets indistinguishable in appearance from the nitroglycerin used in the study. The results were compared with those ascertained two minutes after sublingual administration of fresh and old (three to eleven years old) tablets of nitroglycerin.

The amount of exercise necessary to induce angina, under the standardized conditions of the test when either no medication or blank hypodermic tablets were administered, varied in all but 1 case between 5 and 17 per cent of the average exercise tolerance for the patient. The clinical effectiveness of nitroglycerin was indicated by an increase in exercise tolerance of 25 to 100 or more per cent over the maximum amount of work possible under the control conditions.

RESULTS

The sublingual administration of fresh hypodermic tablets of nitroglycerin prior to exercise increased the exercise tolerance of each patient by 25 to 100 per cent or more (Table 1). The increment of exercise induced by each preparation of nitroglycerin was essentially the same, despite a dosage range of 0.6 to 0.1 mg, except in a patient (L. S.) who showed a moderate response only to a dose of 0.6 mg. In 2 cases, after the administration of nitroglycerin, the patients were able to exercise to the point of fatigue or development of leg pain without precipitating angina pectoris.

Sublingual administration of blank hypodermic tablets did not result in an increase of ability to work.

The exercise tolerance following the administration of eight different samples of nitroglycerin three to eleven years old was the same as that following fresh nitroglycerin, regardless of the age of the tablets and the lack of special precaution in packaging and storage. The rate at which the tablets dissolved under the tongue was also unaffected by age, since all patients reported that each tablet dissolved in from ten to thirty seconds after the sublingual administration. Similarly, the speed of response was unaffected by age, for all tests were conducted two

result of massive retroperitoneal hemorrhage in the upper abdomen. The most frequent source of the hemorrhage is disease in the kidney and its vessels. The condition is usually fatal. The other type, reported above for the first time, is a retroperitoneal hemorrhage occurring chiefly in the true pelvis and resulting in a tumor causing dystocia and necessitating cesarean section.

The source of the hemorrhage in the case reported was probably one of the hemorrhoidal veins. Such a hemorrhage should not be evacuated, its complete absorption may take months.

THE EFFECT OF AGE ON THE CLINICAL EFFECTIVENESS OF NITROGLYCERIN TABLETS*

ELLIOT L. SAGALL, M.D.,† GEORGE S. KURLAND, M.D.,‡ AND JOSEPH E. F. RISEMAN, M.D.§

BOSTON

THE value of sublingual administration of nitroglycerin for relief of attacks of angina pectoris is well established. Nitroglycerin has also been advocated as a prophylactic—before exercise and so forth—to prevent pain.¹⁻³ Objective measurements of the value of both these therapeutic uses have been reported.^{2, 4, 5}

From a practical point of view, the stability of nitroglycerin tablets is important. In the past, many lots of nitroglycerin have been condemned as substandard, presumably because of deterioration. As a result, fresh tablets are recommended, to be dispensed in tightly stoppered bottles.

The question of deterioration of nitroglycerin is still controversial. No definite standards of freshness have been established, and no simple methods of analysis are available. None of the numerous procedures of chemical or biologic assay used for testing the deterioration of nitroglycerin yield information concerning the most significant clinical aspect—namely, the efficacy in the treatment of angina pectoris. This aspect can be measured readily by determining the exercise tolerance, under carefully standardized conditions, of patients with and without the use of nitroglycerin at varying periods after manufacture.

The purpose of this communication is to report the effect of age and heat on the clinical effectiveness of hypodermic tablets of nitroglycerin as determined in patients with angina pectoris. Only hypodermic tablets were tested because attacks of angina pec-

toris are short in duration, and hence rapidly dissolving hypodermic tablets are preferable to triturated ones.^{2, 3}

The various chemical methods that have been proposed for quantitative analysis of the small amounts of nitroglycerin present in medicinal preparations have been summarized by Hutchinson.⁶ In general, they consist of extraction of the nitroglycerin, its reduction into one or more of its breakdown products (nitrogen, nitrate salts, nitrite salts or ammonia), determination by colorimetric or gaseous analysis of the amount of this product and computation therefrom of the amount of nitroglycerin present in the original preparation. The official assay method of *U S P XII*, for example, consists of repeated ether extraction of no less than twenty finely powdered nitroglycerin tablets, evaporation of the ether and saponification of the nitroglycerin in the presence of potassium permanganate. Devarda's alloy is then added to the mixture, and the nitrate present is thereby reduced to ammonia. This is distilled into a standard solution of sulfuric acid, and the amount of unneutralized sulfuric acid is determined by titration with sodium hydroxide, methyl red being used as an indicator. The amount of nitroglycerin originally present is computed from these figures. Blank determinations with the same quantities of reagents are performed in a similar manner, and the necessary corrections made.

Deterioration of nitroglycerin tablets with age has been investigated by chemical determination of the nitroglycerin content at varying times after manufacture. The results, however, are controversial. Scoville,⁷ Smith⁸ and Meek⁹ found significant loss of nitroglycerin in tablets assayed up to four years after manufacture, whereas Bergenaui,¹⁰ Rippetoe and Smith,¹¹ Vanderkleed,¹² Snyder¹³ and Francis¹⁴ reported no significant loss in tablets assayed at periods up to eight years after manufacture.

ie divergent results were due in some degree to the reliability of the chemical methods available. Technical difficulties arising from the small amounts of material used, impurities in the framework of the tablets and errors arising from colorimetric analysis are a few of the factors that contributed to the unreliability of these reports.

The fall in blood pressure in anesthetized rabbits after intravenous administration of small amounts of nitroglycerin was utilized as a method of biologic assay for nitroglycerin deterioration by Edmunds and Roth¹⁵. On the basis of their findings they concluded that tablets not more than two years old had lost practically none of their strength but that older tablets had deteriorated to some extent.

Although the results of chemical and biologic assay methods when applied to the question of deterioration of nitroglycerin with age have not been conclusive, it is generally believed by pharmaceutical manufacturers and clinicians that nitroglycerin is not a stable preparation. Accordingly, current medical opinion, as expressed in leading textbooks of cardiology and general therapeutics, recommends that patients employing nitroglycerin for the treatment of angina pectoris discard old tablets and purchase fresh ones every three to six months.

MATERIAL AND METHODS

The clinical potency of readily soluble hypodermic tablets of nitroglycerin of varying age in doses of 0.6, 0.4, 0.3, and 0.1 mg (1/100, 1/150, 1/200 and 1/500 gr) were investigated. Fifteen different preparations were tested. Three were fresh tablets (less than two months old). Three others had been on the laboratory shelves in pasteboard pillboxes for periods ranging from three to five years. Five were obtained from the shelves of retail drugstores and pharmaceutical houses, where they had remained for four to eleven years, no special precautions against deterioration had been taken in packaging and storage. Three samples originally less than two months in age were kept in pasteboard pillboxes in an incubator at 37° C for three additional months to ascertain the effect of heat on their clinical effectiveness. The remaining sample consisted of fresh readily soluble hypodermic tablets (0.3 mg) that had been kept in a loosely fitting screw-cap vial and carried by 2 patients for four months close to the body in the same vest or trousers pocket used for carrying their clinical supply of nitroglycerin.

Five male patients with angina pectoris, who had demonstrated a moderate to marked response following sublingual administration of nitroglycerin, were selected for these studies. The patients had been followed in a special clinic at weekly intervals for periods ranging from six months to eleven years. The amount of exercise each patient could perform before developing an attack of angina pectoris, as demonstrated by the standardized exercise tolerance test, had been determined on many occasions ac-

cording to a method previously described¹⁶. The exercise, which consisted in mounting and descending a two-step staircase in a room maintained at a temperature of 45 to 50° F, was carried out approximately an hour after the patient had had a light breakfast and had rested for half an hour in the clinic. Only one test was attempted on any given day. The number of trips each patient could perform gave a measure of the exercise tolerance. During the period of study the patients were given only placebo medication except for nitroglycerin as needed in their everyday activities.

The exercise tolerance as determined on many occasions without medication was used as the control for the subject concerned. As a further check the exercise tolerance was measured two minutes after the sublingual administration of blank hypodermic tablets indistinguishable in appearance from the nitroglycerin used in the study. The results were compared with those ascertained two minutes after sublingual administration of fresh and old (three to eleven years old) tablets of nitroglycerin.

The amount of exercise necessary to induce angina, under the standardized conditions of the test when either no medication or blank hypodermic tablets were administered, varied in all but 1 case between 5 and 17 per cent of the average exercise tolerance for the patient. The clinical effectiveness of nitroglycerin was indicated by an increase in exercise tolerance of 25 to 100 or more per cent over the maximum amount of work possible under the control conditions.

RESULTS

The sublingual administration of fresh hypodermic tablets of nitroglycerin prior to exercise increased the exercise tolerance of each patient by 25 to 100 per cent or more (Table 1). The increment of exercise induced by each preparation of nitroglycerin was essentially the same, despite a dosage range of 0.6 to 0.1 mg, except in a patient (L. S.) who showed a moderate response only to a dose of 0.6 mg. In 2 cases, after the administration of nitroglycerin, the patients were able to exercise to the point of fatigue or development of leg pain without precipitating angina pectoris.

Sublingual administration of blank hypodermic tablets did not result in an increase of ability to work.

The exercise tolerance following the administration of eight different samples of nitroglycerin three to eleven years old was the same as that following fresh nitroglycerin, regardless of the age of the tablets and the lack of special precaution in packaging and storage. The rate at which the tablets dissolved under the tongue was also unaffected by age, since all patients reported that each tablet dissolved in from ten to thirty seconds after the sublingual administration. Similarly, the speed of response was unaffected by age, for all tests were conducted two

minutes after sublingual administration of the tablets

The tablets that had been stored in pasteboard pillboxes in the incubator at 37° C for three months showed complete loss of clinical potency. The amount of exercise each patient could perform after

ness of the preparations tested regardless of their actual nitroglycerin content. This method, which has been used in this clinic for over ten years, has been found to offer a satisfactory objective measure of the effect of various medications in patients with angina pectoris.^{17, 18} By employing the patient him-

sublingual administration of these tablets in dosages of 0.6, 0.3 and 0.1 mg was essentially the same as that performed without medication or following administration of blank hypodermic tablets.

The tablets that had been carried close to the body for four months showed no loss of clinical potency.

DISCUSSION

Direct transference of the results of chemical or biologic assay methods to the problem of clinical potency of old nitroglycerin preparations is not justifiable. It has been shown that for all practical purposes 0.3 mg is as effective as larger doses and, furthermore, that tablets containing as little as 0.1 mg of nitroglycerin are of clinical value.^{2, 3} A decrease in the nitroglycerin content of old tablets, therefore, may not indicate a corresponding reduction of clinical value in patients with angina pectoris.

The clinical response following sublingual administration of nitroglycerin in 4 patients was essentially the same in dosages ranging from 0.6 to 0.1 mg. On that basis it might be postulated that old tablets of 0.6 mg could lose up to 80 per cent of their nitroglycerin and still retain clinical potency and value. To determine if this were so, the nitroglycerin content of several 0.6-mg tablets employed in this investigation was determined by the *U S P* method of chemical assay (Table 2). Comparison of the content of the three old samples with that of the fresh tablets showed no significant loss of nitroglycerin. Furthermore the results in a patient (L S) who responded to 0.6 mg but not to a dose of 0.4 mg or smaller indicate that 0.6-mg tablets as old as nine years failed to deteriorate appreciably in clinical value.

The method of biologic assay employed in this investigation gave a measure of the clinical effective-

ness of the preparations tested regardless of their actual nitroglycerin content. This method, which has been used in this clinic for over ten years, has been found to offer a satisfactory objective measure of the effect of various medications in patients with angina pectoris.^{17, 18} By employing the patient him-

self as a means of testing clinical efficiency the procedure avoids the difficulties that are inherent in the chemical or biologic methods of assay previously employed. With the exception of the tablets exposed to heat, all preparations, regardless of age, showed no loss of clinical potency. These results indicate that, under ordinary conditions of storage in a retail drugstore, hypodermic tablets of nitroglycerin retain their clinical effectiveness for many years. Further

more, under ordinary conditions of use by patients, they retain their effectiveness for at least four months. Therefore, it is not necessary for patients to purchase fresh supplies at more frequent intervals.

Tablets exposed to heat, however, rapidly lose their clinical effectiveness. This fact should be kept in mind when nitroglycerin preparations are stored. The tablets do not lose their clinical potency if kept at room temperature, but if they are kept near steam pipes, radiators and so forth, they are apt to suffer deterioration.

SUMMARY

The clinical effectiveness in patients with angina pectoris of eleven preparations of hypodermic tablets

nitroglycerin, in dosages ranging from 0.6 to 0.1 g, were assayed at periods varying from a few months to eleven years after manufacture. No particular precautions against deterioration had been observed in the packaging and storage of these tablets. There was no essential loss of clinical effectiveness in the old tablets as compared to fresh tablets of the same dosage.

Fresh tablets exposed to heat (37° C) for three months showed a complete loss of clinical potency, whereas tablets that had been carried by patients in the customary manner for four months showed no loss of clinical effectiveness.

MEDICAL PROGRESS

THE DIAGNOSIS OF CANCER OF THE PANCREAS*

FRANZ J. INGELFINGER, M.D.†

BOSTON

TEN years ago Clute¹ discussed the problems presented by the diagnosis and treatment of cancer of the pancreas. In the intervening decade surgical treatment has progressed remarkably,²⁻⁴ but diagnosis is still lagging, partly owing to the variability of pancreatic symptoms, the inaccessibility of the pancreas to examination, the difficulty of x-ray study of this gland and the unavailability of an easy and reliable function test. On the other hand, failure to recognize the symptoms that have been repeatedly emphasized in the literature of the last ten years and to institute such tests as have been made available are also responsible for the late recognition of pancreatic carcinoma.

The intimate anatomic relation of the head of the pancreas to the ampulla of Vater and its adjoining structures (the papilla of Vater, the terminal common bile duct, the duct of Wirsung and the duodenal mucosa covering the papilla) makes the exact site of origin of many cancers in this area uncertain. Although occasionally possible, the clinical differentiation between cancers of the pancreas and those of the ampullary region is particularly difficult. Any clinical consideration must consequently encompass neoplasms arising at both sites. Cancers of the islands of Langerhans, on the contrary, are charac-

terized by a different syndrome and are not included in this discussion.

The literature as reviewed by Leven⁵ in 1933 indicated that cancer of the pancreas afflicts the usual cancer age group between forty and seventy, attacks men two or three times as frequently as women and occurs roughly once in every thousand hospital admissions. Berk's⁶ extensive review in 1941 confirmed these figures. He was also led to conclude that "carcinoma of the pancreas causes 1 to 2 per cent of all deaths in the population at large," a somewhat puzzling statement because Berk at the same time agreed with previous writers that cancers of the pancreas account for 1 to 2 per cent of all cancers. Since the publication of Berk's review, a number of articles have dealt with the incidence of pancreatic carcinoma,⁷⁻¹³ but no trends have been observed that challenge the principal conclusions reached by Leven and Berk. It is to be noted, however, that youth provides no guarantee against pancreatic neoplasm. In 113 cases collected in two series 6 patients were under the age of forty,^{7, 13} and up to 1941, pancreatic or periampullary cancer had been reported nine times in patients less than twenty years old.⁹ Periampullary carcinoma, in particular, may appear in younger persons.¹⁴

Although opinion regarding the general incidence of pancreatic carcinoma is quite consentaneous, statements on the relative incidence of cancers of the

†Associate professor of medicine, Boston University School of Medicine, visiting physician, Massachusetts Memorial Hospitals.

ampullary area, of the head and of the body and tail of the pancreas are more conflicting. The diverse results reported by various authors probably depend on two factors: the methods used in making the diagnosis, and the type of material included in the study. Diagnoses made on purely clinical grounds are obviously subject to error, but incorrect conclusions may also be drawn after the pancreas is palpated at operation and a biopsy taken.³ Accurate diagnosis is made possible only by autopsy or by operative procedures that resect large blocks of tissue. The experience of Ransom¹⁵ is illustrative of 10 patients examined at laparotomy, 6 were considered to have pancreatic carcinoma and 4 ampullary neoplasms, whereas autopsy revealed that only 3 of these patients had cancer of the pancreas, in 7 cases the primary site was the common bile duct.

Whether the diagnosis is made at operation or post mortem also affects the material included in an analysis of cases. Patients observed at operation contain a preponderance of cancers of the ampulla or of the head, for cases of this type present symptoms calling for operative intervention. Cattell,³ for example, states that carcinoma of the ampulla is more frequent than that of the pancreas. A series based on material at autopsy, however, may reveal that lesions of the tail of the pancreas occur much oftener than one would suspect after analyzing surgical material.¹⁶ Finally, the diffuse nature of many pancreatic cancers makes it merely a matter of individual opinion whether or not the primary lesion is placed in the head.⁶ As a rough approximation, however, one may expect to see three cancers of the head of the pancreas for every one that involves the body and the tail. The relative frequencies of pancreatic and periampullary lesions are indicated by the following figures: cancers of the pancreas have been reported in 0.30 to 0.75 per cent of all autopsies,⁶ whereas the incidence of periampullary carcinomas is said to range from 0.04 to 0.20 per cent.^{17, 18} of all post-mortem examinations.

For many years it has been the practice to separate cancers in the head of the pancreas from those in the tail on the basis of clinical and pathological differences. The wisdom of this practice has been challenged by Berk,⁶ who emphasizes the difficulty of diagnosing and delineating pancreatic neoplasms, and who suggests that overemphasis of the single symptom of jaundice interferes with a broad conception of the symptoms and signs to be expected in all cases of pancreatic cancer. Another frequently quoted difference — that cancers in the ampulla or head grow slowly and metastasize late, whereas those in the body and tail grow and spread rapidly — may be more apparent than real. That this difference has been observed at autopsy or at operation is unquestioned. In 28 patients dying of ampullary carcinoma, Baggenstoss¹⁸ found no evidence of metastases in 15, in the 16 cases of cancer of the body or tail reported by Duff,¹⁶ metastases were present

in all but 1. Perhaps an intrinsic difference between the two lesions exists, but the influence of other factors is excluded with difficulty. Lesions in the head of the pancreas usually obstruct the hepatic or pancreatic ducts, and the resultant chain of events leads either to surgery or to death on the basis of hepatic or pancreatic failure before the neoplasm has a chance to grow or spread. In cancers of the body and tail, however, no vital processes are disrupted by the primary growth, and the patient slowly dies of cachexia and inanition as the cancer invades and metastasizes. This rather obvious explanation of the apparent difference between cancer in the head and tail of the pancreas has, of course, been recognized by various writers but has been dismissed as a contributory factor on the basis of various theoretical arguments.^{18, 19} That the dismissal is somewhat premature, however, is indicated by the observations of Orr,²⁰ who successfully removed periampullary carcinomas in 8 patients, 5 of whom subsequently died of metastases.

Heterotopic pancreatic tissue occurs in various portions of the digestive tract, but the duodenum, stomach and jejunum are the most frequent sites. Like other pancreatic tissue, these aberrant cells are subject to malignant degeneration²¹ and may account for some of the cancers of the small bowel.²²

The factors that make it difficult to collect accurate statistics on the pathology of pancreatic and ampullary cancers also introduce discrepancies into an analysis of the symptoms produced by these diseases. The incidence of jaundice may serve as illustration. Since this finding is the usual reason for surgery in patients with pancreatic neoplasm, its occurrence in surgical material is practically constant. Except in pancreaticoduodenectomy the surgical diagnosis of cancer of the pancreas depends on palpation of a nodule or mass in the head of the gland, metastases or an occasional biopsy attesting to the malignant nature of the process. In a series of surgical cases jaundice is consequently found to be the outstanding symptom of pancreatic carcinoma. A pathologist, however, might classify many of the nodules in the head of the pancreas as periampullary neoplasms. Deprived of these cases and increased by relatively nonicteric cases of pancreatic cancer, a series studied at autopsy reveals that jaundice is a frequent but far from invariable symptom of pancreatic cancer.

The marked effect that the diagnostic method may have on the observed incidence of a symptom and the variability of the methods from one series to another suggests that the true incidence of jaundice — or of any other symptom — cannot be derived merely by the process of averaging the incidences reported by all who have discussed cancer of the pancreas. Such averages are at best approximations, and the assignment of an exact figure carried to two decimal places to the incidence of any symptom of pancreatic cancer seems to impart an

warranted aura of accuracy. Nevertheless, three symptoms occur so frequently that there is no doubt concerning their prevalence. These symptoms are weight loss, pain and jaundice.

Weight loss, sometimes totaling as much as 50 pounds, is almost invariably evident, only a rare case report states that the patient had lost no weight when first seen.^{23, 24} One may question whether this loss, particularly one of 20 pounds or more, does not indicate advanced disease and preclude operability. In some cases weight loss carries such an implication, especially if the neoplasm arises in the body or tail of the pancreas. In others, however, weight loss occurs because a small periampullary neoplasm obstructs the flow of digestive juices. In lesions of this type weight loss certainly does not contraindicate operation, as is evident from Cattell's³ figures. Of 18 patients who were subjected to pancreatic resection, 16 had experienced preoperative weight loss, 13 had ampullary lesions and 13 enjoyed what appeared to be a successful result. When weight loss is the manifestation of a carcinoma in the head of the pancreas, its significance is variable; it may mean that the growth is inoperable, but it may also be the result of an associated diabetes, or of a widespread destruction of the acinar elements or of secondary gastrointestinal disorders such as nausea and diarrhea. A patient whose case was recently reported, for example, had lost 50 pounds because of an extensive pancreatic cancer, yet a total pancreatectomy was feasible, and the patient appeared to be doing well a year after operation.²⁵ One must conclude that progressive weight loss is an important symptom not only of all pancreatic cancers but also of those susceptible to operative removal.

Pain ranks as the second most significant symptom of cancer of the pancreas. The association of painless jaundice with pancreatic carcinoma seems to be so firmly rooted in the medical mind that almost every recent writer on this subject has felt it necessary to emphasize repeatedly that at least three fourths of the patients with cancer of the pancreas do have pain. Ampullary cancers are said to occasion less pain and are held responsible for many cases of painless jaundice,^{3, 9, 26} but in one series more than half the patients studied complained of pain.¹⁰ The character of the pain in pancreatic or ampullary cancer is extremely variable and can be misleading in that it may mimic biliary or intestinal colic. In many cases, however, its features are almost specific: it is dull, boring and often severe. It is located in the upper abdomen, either on the right or on the left, and radiates through to the back.^{27, 28} It is not related to eating, bowel movements or physical activity, but is often aggravated when the patient lies on his back. In such cases the patient usually complains that the pain is worse at night, and the attending physician may find "a nervous, apprehensive patient sitting up in bed,

bending forward over folded arms which rest against his epigastrium, and maintaining his position hour after hour because it gave the most relief from pain."²⁴ Cases of this type should be suspected of being cancer of the pancreas and should not be classified as psychoneurosis or back strain.

Careful pathological examination indicates that neoplastic invasion of nerves occurs in many cases of pancreatic carcinoma.²⁹ In addition to the deep somatic nerves, the celiac plexus of sympathetic nerves is presumably most subject to invasion by reason of its position adjacent to the pancreas. Since both the somatic and sympathetic nerves can transmit pain impulses, it is possible that back pain in pancreatic cancer is produced in part by neural invasion. Actually, a fair but not a perfect correlation between back pain and invasion of the nerves has been found.²⁹

Whether or not jaundice occurs as an early symptom depends, of course, on the site of the lesion. Thus the fact that obstructive jaundice develops early in about two thirds of the cases merely expresses the relative incidence of lesions in or near the terminal portion of the common duct. Late in the course of pancreatic cancer, jaundice becomes a frequent symptom, even when the primary lesion originates in the body or the tail, but jaundice in these cases merely indicates that the disease is advanced, with extensive metastases to the liver and to the lymph nodes surrounding the extrahepatic bile ducts.

The jaundice that occurs early is usually steadily progressive and obstructive. It is not an invariable concomitant of cancer of the head of the pancreas, however, nor is it always of a steadily progressive character.⁹ Ampullary cancers in particular may produce an inconstant icterus, for these lesions, which are situated near the orifice of the common duct, are subject to necrosis and sloughing and thereby allow an intermittent flow of bile.¹⁴ In a series of 40 cases of ampullary carcinoma, jaundice was fluctuating in 32 and intermittent in 8.¹⁰

Since jaundice occurs early in only 2 out of 3 cases of pancreatic cancer and since only 1 out of 4 patients is free from pain, it follows that painless jaundice is not a frequent characteristic of cancer of the pancreas. Berk⁶ estimates its incidence at about 20 per cent. When it does occur, it presents a symptom complex that is significant for the diagnosis of pancreatic or ampullary cancer. Perhaps because of this fact, it continues to be stressed in the literature in a way that is completely out of proportion to its incidence. In one report, for example, "painless obstructive jaundice, with diminished or absent ferments," is considered to favor the diagnosis of carcinoma of the pancreas, but the case summaries reveal that of 12 patients with cancer of the pancreas studied, 8 complained of pain.³⁰

In addition to weight loss, pain and jaundice, pancreatic cancer may give rise to a number of other

symptoms and signs, many of which, such as anorexia, weakness, edema and fever,^{12, 31} are nonspecific and do not help in reaching a diagnosis. Gastrointestinal symptoms of all types are of course prevalent, one of the most frequent being a change of bowel habits. Constipation predominates over diarrhea. It has been suggested that a normal red-cell count and the absence of occult blood in the stools of a patient who otherwise presents symptoms suggesting upper gastrointestinal cancer should make one suspicious of pancreatic neoplasm.⁶ Although this is true of many patients, others may vomit blood or may exhibit melena for one of the following reasons: the pancreatic cancer may have eroded into the stomach or duodenum, esophageal varices may have formed secondary to neoplastic invasion and thrombosis of the splenic or portal vein, hypoprothrombinemia may exist because of obstructive jaundice, and a primary lesion at the ampulla may have become ulcerated. Ulceration of ampullary carcinoma was described in 57 of 222 cases collected by Lieber, Stewart and Lund,¹⁴ and in 40 cases analyzed by Sharpe and Comfort,¹⁰ 25 patients had either tarry stools or stools containing occult blood.

"I have several times, in the wards, — pointed out to you that obliterative phlebitis is not a symptom which belongs peculiarly to cancer of the stomach, but that it is equally symptomatic of cancer of any other internal organ." These words of Trousseau³² were echoed about seventy years later by Sproul,³³ whose analysis of material at autopsy indicated that between 15 and 25 per cent of patients with most varieties of abdominal cancer suffer from venous thrombosis in the abdomen or legs. In 16 cases of cancer of the body or tail of the pancreas, however, venous thromboses were found in 9—more than twice the incidence of such thromboses with gastric cancers or with cancers in the head of the pancreas. In some cases the tendency toward thrombosis was apparently so pronounced that nonbacterial vegetations formed on the heart valves, a phenomenon that was subsequently observed in another typical case of cancer of the pancreatic tail and body.³⁴ Sproul and later Kenney,¹⁹ impressed by the frequent association of venous thromboses and neoplasms in the tail and body of the pancreas, concluded that these growths *per se* must affect the clotting mechanisms of the blood. As yet, this hypothesis has not been proved, nor has the progressive but relatively prolonged cachexia typical of cancers in the tail and body been ruled out.³⁵ Furthermore, the increased incidence of thrombosis in cancers of the body and tail of the pancreas as compared with that in those of the head may also indicate that lesions in the head produce a decreased clotting tendency, a possibility that must be considered in view of the hypoprothrombinemia that attends obstructive jaundice.

In these days of marked emphasis on psychosomatic disorders, it is well to point out that neurotic patients with pancreatic carcinoma are almost invariably suspected of having a marked psychoneurosis, partly because of the negative results obtained after the physician has exhausted his usual diagnostic armamentarium. But the situation is often more complex, for Yaskin³⁶ and subsequently others^{24, 37} reported cases of pancreatic cancer in which competent psychiatrists made diagnoses of advanced states of anxiety or depression. The association of pancreatic cancers, especially those of the body and tail, with psychiatric abnormalities does not establish a causal relation, but it does carry a warning: progressive anorexia, weight loss and back pain suggest cancer of the pancreas, regardless of whether the patient has psychiatric manifestations at the same time.

The physical signs of pancreatic cancer are manifold and depend on the location, size and spread of the tumor. A palpable mass may be discovered on rare occasions before the cancer has spread, but this finding usually indicates inoperability as much as do a rectal shelf, ascites, abdominal varices and obvious metastases to the liver, lungs or lymph nodes. A sign that may occur early and to which much interest pertains is a palpable gall bladder in patients who exhibit obstructive jaundice. This sign, of course, is linked with the name of Courvoisier, whose law, as translated literally by Ramsom,¹⁵ is as follows:

With obstruction of the common duct by stone, dilatation of the gall-bladder is rare, the organ is usually shrunken. With obstruction of other kinds, on the contrary, distention is the rule, shrinking occurs in only one twelfth of these cases.

Opinions regarding the reliability of Courvoisier's law differ widely in that palpable gall bladders have been noted by some authors^{8, 9} in less than 10 per cent of jaundiced patients with cancers in the ampulla or pancreatic head. Others, however, have palpated a distended gall bladder in 62 per cent of these cases. Reviews of the literature indicate that on the whole a distended gall bladder can be detected clinically in about half the cases of pancreatic cancer with jaundice,^{6, 14} but that at autopsy or operation enlarged and tense organs are found in about four fifths of the cases.^{6, 10, 15} The discovery of a large, relatively nontender gall bladder in a patient with obstructive jaundice may therefore be regarded as evidence for a neoplastic obstruction of the extrahepatic biliary passages, but a negative finding—that is, failure to palpate the gall bladder—is of little help in ruling out this diagnosis. A not inconsiderable number of patients have both gallstones and pancreatic cancer, a combination that makes the diagnosis extremely difficult.¹⁴

The following laboratory tests are significant in the diagnosis of pancreatic carcinoma: stool exami-

ation for excess fat and protein, determination of glucose in blood and urine, analysis of serum and duodenal contents for pancreatic enzymes and, if jaundice is present, the establishment of its obstructive character

As has been known for many years, a diffuse carcinoma involving the whole pancreas or a small lesion so situated as to block the pancreatic ducts may impair the digestion of fat and proteins, which consequently appear to excess in the feces. The stools are then light colored, greasy and bulky, the weight of the stools occasionally reaching five times normal.³⁸ In spite of the fact that steatorrhea and creatorrhea are well established findings in cancers of the pancreas, little information exists regarding the frequency of their occurrence. After reviewing the literature, Berk⁶ concluded that less than 10 per cent of patients with pancreatic cancer pass fatty stools. One must remember, however, that most series of cases are taken from hospital files, are rarely studied by the author himself, are often not suspected of having pancreatic cancer during life, and that "rarely, even in leading hospital clinics, are the stools adequately examined."³⁸ On the other hand, steatorrhea and creatorrhea occur rather late in the course of pancreatic disease,³⁹ and some patients may have fairly normal stools, even after complete pancreatic atrophy⁴⁰ or resection.⁴¹ A rough estimate indicates that a fourth of the patients with ampullary or pancreatic carcinoma pass fatty stools with a high nitrogen content, but that unless the patient is jaundiced — that is, obstruction is present in the ampullary area — steatorrhea and creatorrhea indicate advanced disease.

Precise analyses of stools are troublesome to carry out, not the least difficulty being a quantitative three-day stool collection, but if facilities are available, quantitative analyses for fat and nitrogen are of great help. Normal persons usually excrete less than 5 per cent of the fat intake and rarely pass more than 12 gm of fat in the stools a day.⁴² In pancreatic steatorrhea 30 to 50 per cent of the intake may be lost in the stools. (It should be noted that excretions of fecal fat expressed in absolute values, such as grams per day and percentage of intake, are significant, fecal fat expressed as percentage of dry weight of the stool gives a rough index but is not completely satisfactory, since the percentage of fat varies inversely with the amount of other material in the dried stool.)

Although facilities for quantitative measurement of the daily fecal fat loss may not be available, there is little excuse for not staining a stool sample with an alcoholic solution of sudan III. This stain imparts a red or orange color to fat droplets and to some crystalline and amorphous lipid material, although the orange-staining fatty-acid crystals frequently described in laboratory manuals are rarely seen. A careful study by Andersen⁴³ showed that

the amount of sudan-staining material is an excellent indication of the percentage of fat present in the stool but only a fair indication of the total fecal fat. She concludes that a negative finding (less than 2 fat droplets per low-power field) and a ++++ finding (about half the visible material stained with sudan) are highly significant. When mineral oil is used, the test is unreliable. Another important contribution made by Andersen are her observations suggesting that bacteria in the colon split neutral fats. This explains why patients with pancreatic deficiency excrete so much split fat in the stools, when one would expect the deficiency in lipase to result in a large output of unsplit, neutral fat.

Pratt³⁸ believes that pancreatic deficiency in protein digestion can be detected by the identification of meat fibers on microscopic examination of the stool. Other investigators⁴⁴ consider the presence of meat fibers less significant, since they may be found in other forms of diarrhea and since the digestion of meat is related to gastric as well as pancreatic function. The question is important, for the amount of nitrogenous material excreted in the feces provides a good means of separating pancreatogenous steatorrhea from that of sprue or pure biliary obstruction.⁴² In normal persons and in patients with nonpancreatogenous steatorrhea, the daily fecal nitrogen excretion is less than 3.0 gm, in patients with pancreatic deficiency the creatorrhea exceeds this amount.⁴⁵

Cancer of the pancreas and abnormalities in carbohydrate metabolism occur together more frequently than can be accounted for on the basis of chance. The reported figures on the coincidence of these diseases vary widely, but again the differences may depend on the criteria used in diagnosing diabetes, — glycosuria, an elevated fasting blood sugar or an impaired glucose-tolerance curve. Using the glucose-tolerance test, Berk⁶ found abnormal results in 7 out of 9 cases, but an elevated curve was found in only a fifth of the cases he collected from the literature. This ratio corresponds to the average incidence of glycosuria and fasting hyperglycemia reported by various subsequent writers, but the individual figures vary from zero⁹ to 30 per cent.⁷ The situation is analogous to that pertaining to fatty stools: evidence for diabetes increases in proportion to the effort made to uncover abnormalities of sugar metabolism.

At first glance, the association of pancreatic carcinoma and a diabetic condition seems obvious. Actually the situation is more complex. Even with extensive neoplastic replacement of acinar tissue, the islands of Langerhans may be spared.⁴⁶ ⁴⁷ So far as can be judged from the pathologic picture, consequently, many cancers of the pancreas are not diffuse enough to account for an associated diabetes. Furthermore, in many cases, the diabetes antedates the symptoms of pancreatic cancer by many years.⁴⁷ ⁴⁸ In keeping with this fact, Marble⁴⁷ found

that in 256 patients who suffered from both diabetes and cancer, pancreatic cancer, which was definitely proved in 21, accounted for 8 per cent of all carcinomas in the diabetic cases as compared with 1 or 2 per cent in the population at large. These figures suggest the possibility that diabetes is occasionally the precursor of cancer of the pancreas, rather than vice versa. Although a definite causal relation between diabetes and pancreatic cancer cannot be established, the two conditions coexist frequently enough for any suggestion of a diabetic state to intensify suspicion of pancreatic cancer if the clinical picture is otherwise suggestive.

With the development of methods for determining the concentrations of pancreatic enzymes in the blood and the duodenal contents, it was hoped that the diagnosis of pancreatic disease would be greatly facilitated. This hope has been realized only in part, for results well within the normal range may be obtained unless the cancer obstructs the pancreatic ducts or destroys more than half the pan-

Similar results can be expected in patients with tumors of the ampulla.⁵² As has been emphasized, an elevated serum lipase or amylase implies pancreatic disease,⁵² but not the type, a clear-cut dissociation, however, with a persistently high lipase and a normal amylase, suggests cancer.⁴⁹ Some cases of an obstructing ampullary lesion with initially elevated values for serum lipase may eventually display values in the low normal range, since the obstructed acinar cells atrophy or are invaded by neoplasm. A cancer of the pancreatic acini with function is rare, but such a case has apparently been observed,⁵³ since the concentrations of the serum amylase and lipase were, respectively, nearly one hundred times and ten times the normal values.

On the basis of experiments performed with dogs, Popper and his associates^{54, 55} suggested that valuable information could be obtained from serum enzyme determinations after stimulation with an intravenous injection of secretin and a subcutaneous dose of acetyl-beta-methylcholine chloride (Mecho-

TABLE 1 Data in 37 Cases of Pancreatic Cancer Reported in the Literature

AUTHOR	TOTAL NO OF CASES	SITE OF CANCER	REDUCTION IN VOLUME AND BICARBONATE SECRETION	REDUCTION IN TOTAL ENZYME OUTPUT	ICTERUS
Agren and Lagerlof ⁵⁶	7	Head, 6 Body, 1	3	4	4
Bauman and Whipple ⁵⁰	11	Head, 9 Not stated, 2	Not stated	10	7
Pollard, Miller and Brewer ⁵⁹	6	Head, 5 Tail, 1	3	3	Not stated
Friedenwald and Morrison ¹¹	8	Not stated	Not stated	5	Not stated
Diamond and Siegel ⁶⁰	3	Head, 3	2	3	3
Pratt, Brugsch and Rostler ⁶¹	2	Head, 2	2	2	2

creatic acini. Another, somewhat different, source of difficulty is the great number of methods and modifications of methods used by various investigators. Some standard methods of determining and some standard units of expressing concentrations of pancreatic enzymes must be adopted before the value of this analysis can be appraised.

Determination of the serum amylase (diastase) concentration has occasionally yielded a high figure in cases of pancreatic cancer, but on the whole not much help can be expected from this test.^{44, 49} The urine amylase content, which fluctuates more than the serum content, is even less significant.^{38, 48} Determination of serum lipase, by contrast, is of the greatest value. In the Cherry-Crandall⁶⁰ method, which is almost universally used, the lipase content of the serum is expressed as the number of cubic centimeters of 1/20 normal sodium hydroxide solution necessary to neutralize the fatty acids formed by the action of 1 cc of serum on an olive-oil substrate. Johnson and Bockus,⁵¹ who placed the upper limit of normal for this test at 10 cc, found an elevated lipase in 16 out of 30 cases of pancreatic cancer "at least once during the course of the illness." Even if 15 cc is used as the upper limit of normal, an elevated serum lipase is found in about half the cases of pancreatic cancer.^{49, 52}

lyl). If this stimulation fails to elevate the serum concentrations of amylase and lipase, the authors believe, pancreatic hypofunction may be suspected. On the other hand, elevation of the serum lipase after an intravenous injection of secretin insufficient to alter the level in a normal subject suggests obstruction of the pancreatic ducts.

The pancreatic secretion in cases of pancreatic cancer may be reduced in volume and may contain a decreased concentration of bicarbonate, amylase, trypsin and lipase. The reductions are often noticeable in the fasting secretions, but the deviation from normal is more apparent if the pancreas is stimulated with secretin or acetyl-beta-methylcholine chloride. The former has been relatively unavailable, but the results obtained with the latter should be equally if not more satisfactory, since the drug stimulates a secretion of normal volume but of increased enzyme concentration,⁵⁶ and it is stated that the enzyme output is the first to suffer in pancreatic disease.⁵⁷ Over half the cases of pancreatic cancer are reported to exhibit a decreased enzyme concentration in the duodenal juices (Table 1). Possibly a somewhat false impression of the value of the test in the early diagnosis of pancreatic cancer is given by the data, for cases with advanced disease are included. Nevertheless, analysis of the duodenal

contents for pancreatic ferments after stimulation with secretin or acetyl-beta-methylcholine chloride yields invaluable information, particularly since depression of pancreatic enzymes may precede the onset of jaundice or steatorrhea.^{39 53 62}

Scattered case reports indicate that the sedimentation rate is elevated in advanced cases of cancer of the pancreas, but this test usually gives normal results when the lesion is small and localized.^{39 53}

When a patient is icteric, it is the function of laboratory tests to determine the type and course of the jaundice. Jaundice that results from pancreatic or ampullary cancer is typically progressive, nonfluctuating and obstructive—that is, the stools remain acholic, the heavily bile-stained urine contains no urobilinogen and almost all the serum bilirubin can be quantitated with the direct van den Bergh reaction. The completeness of the obstruction produced by the usual neoplastic invasion or compression of the external biliary passages is reflected in the fecal urobilinogen content. Measured by Watson's⁶³ method, the daily fecal output of urobilinogen in patients with obstructive jaundice caused by carcinoma is less than 5 mg, in those with noncancerous jaundice of the obstructive type—caused by common-duct stones, strictures, pancreatitis or severe hepatitis—the urobilinogen output in the stools is greater. Although this test is helpful in the diagnosis of many pancreatic or ampullary cancers,⁶⁴ the results may be misleading in cases of ampullary tumors that exhibit fluctuating or even intermittent jaundice.

Since there is no method of direct x-ray study of the pancreas, the roentgenographic demonstration of tumors in this organ depends on abnormalities produced in its adjoining hollow viscera. A small intrapancreatic or a diffuse scirrhous cancer that replaces the normal tissue without concomitant enlargement of the gland may consequently go undetected in spite of painstaking radiologic examination. Large tumors may displace the stomach upward and ventrally, the descending duodenum laterally and the transverse duodenum and transverse colon downward.^{26 65} Of these deformities, a large C-shaped duodenal loop is perhaps the best known, but its interpretation is often difficult, especially in hypersthenic persons. In patients of this habitus, the stomach is usually stretched across the spine high in the epigastrium and thus exposes the whole duodenal loop, which has an appearance of enlargement.

Massive displacement of the adjoining viscera by a pancreatic cancer is a poor prognostic sign, since it suggests a large and advanced neoplasm. Smaller cancers situated in the periphery of the pancreas may, however, manifest themselves by the production of localized deformities in the gastrointestinal tract. Changes in the mucosal pattern or alterations in the finer outlines of the stomach or duodenum may appear before the cancer has invaded

the mucosa, later filling defects and evidence of ulceration may develop as the tumor extends into the lumen of the bowel. So far as the duodenum is concerned, considerable attention has been directed to the so-called "reverse figure-3" sign. As originally described by Frostberg,⁶⁶ the entire descending duodenum participates in forming such a sign, the top of the figure starting just beyond the duodenal cap, its lower pole at the beginning of the transverse duodenum and the prong in the middle of the figure pointing toward the spine in the region of the ampulla. Frostberg, who found this duodenal configuration in 1 case each of pancreatitis, of cancer of the pancreas and of cancer of the ampulla, assumed that it was produced by pressure on the medial wall of the duodenum, with relative fixation of the ampullary area. Other authors⁶⁷⁻⁶⁹ have used the reverse figure-3 sign to describe smaller lesions that at times seem to include only the lips of the papilla of Vater, the central prong of the figure being formed by the entrance of the ampulla. Both large and small configurations are sometimes observed in normal duodenum.^{26 66}

When case records of patients with pancreatic or ampullary cancer are reviewed, the incidence of gastrointestinal abnormalities as demonstrated by x-ray examination varies markedly in different series. In some, positive findings are claimed in nearly three fourths of the cases;^{17 47} others report an incidence of about 50 per cent,^{6 7} whereas still others^{5 10 16} consider abnormal roentgenologic findings unusual. Although some abnormality in the radiologic appearance of the stomach, duodenum or colon may be observed in about a third of the cases of pancreatic or ampullary cancers, the findings are diagnostic in a much smaller number, especially if indications of an early lesion are being sought.

A rather ingenious method of visualizing the pancreas was proposed by Engel and Lysholm⁷⁰ twelve years ago. This consisted of having the patient lie prone, inflating the stomach with air through a tube or by giving an effervescent mixture and then taking a lateral roentgenogram. Ideally the gas in the stomach tends to outline the dorsal aspect of this organ, and the pancreas appears as a shadow between the air-filled stomach and the lumbar vertebrae. Using this technic, Engel and Lysholm⁷⁰ and Holm⁷¹ believed that they had obtained positive results in 86 per cent of their cases of pancreatic cancer. Enlargement of the pancreas, however, must be present if positive results are to be obtained by this method, and false-positive reactions may occur in short, thickset persons who have excess retroperitoneal fat.^{70 72}

In patients who have a tube in the common duct after choledochostomy, cholangiography occasionally reveals the presence of a pancreatic cancer by demonstrating a dilated common duct that is cut off rather abruptly at its distal end.^{73 74} If the

head of the pancreas is free of disease, pancreatic reflux sometimes complicates cholangiography, but apparently no tumors of the body or tail have been discovered by this method.⁷⁶ Peroral catheterization of the ampulla of Vater has been tried in cadavers, but must be difficult in patients living.⁷⁶ A method that may hold some hope for the early identification of lesions in the pancreatic head or the ampulla is the nonsurgical cholangiography developed by Royer and Solari.⁷⁷ By this method, the gall bladder and bile ducts are injected with radio-opaque material through a peritoneoscope. Demonstration of an enlarged gall bladder, of dilated biliary passages and of the obstructed end of the common duct is perhaps feasible by this technic in patients suffering from pancreatic or ampullary cancer.

SUMMARY

Improved surgical methods of removing tumors of the pancreas or ampulla of Vater demand early diagnosis of these diseases. In many cases this goal cannot be achieved with present knowledge and technic. In others, the fatal delay that withholds a possible surgical cure from the patient can be avoided by an appreciation of the following facts:

Almost all patients with cancer of the pancreas lose weight rapidly and progressively. Many of them have a boring upper abdominal and back pain unrelated to any gastrointestinal function. Many others have obstructive jaundice. The combination of any two of these symptoms is highly indicative of pancreatic cancer, particularly if the patient is a man over forty years of age.

A palpable, nontender gall bladder in a jaundiced patient is suggestive of cancer in or near the head of the pancreas. The absence of this sign does not exclude pancreatic cancer.

Laboratory tests, as a rule, are helpful when positive and of little significance when negative. Particularly suggestive are the following: a persistent obstructive jaundice, with acholic stools and no urobilinogen in the urine, a high serum lipase and a normal serum amylase, absent or greatly diminished enzymes in the pancreatic secretion stimulated by secretin or acetyl-beta-methylcholine chloride, and stools containing an excess of both fat and nitrogen.

Less significant, but consistent with the diagnosis of pancreatic cancer, are hyperglycemia, glycosuria or impaired glucose tolerance and an elevated sedimentation rate.

At present, the roentgenologic diagnosis of pancreatic cancer depends principally on deformities produced in adjoining hollow viscera. Greater use of new technics may increase the usefulness of the x-ray in the diagnosis.

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

Weekly Clinicopathological Exercises

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., Editor

BENJAMIN CASTLEMAN, M.D., Associate Editor

EDITH E. PARRIS, Assistant Editor

CASE 32441

PRESENTATION OF CASE

A forty-nine-year-old salesman entered the hospital because of severe dyspnea.

At approximately twenty years of age, the patient developed a chancre for which he received intravenous injections of an "antisyphilitic drug" over the course of a year. He was well until three years before admission, when a left Bell's palsy occurred a day following exposure to cold air while he was sleeping outdoors. At about the same time he began to experience shooting pains in the lower back and at times down the legs and arms. Two months before admission he was awakened by a severe precordial pain radiating to the left shoulder. He sweated, felt suffocated and feared impending death. Partial relief was obtained from an injection given by a physician. The patient coughed blood-streaked sputum for four days. There had been no previous cardiac or pulmonary symptoms, although the patient was known to have a systolic

blood pressure of 170. At the end of four days he entered the Emergency Ward, where a Grade II apical systolic and a questionable aortic diastolic murmur were heard. There was no tenderness over the leg vessels. The pupils were fixed, the left one being oval in a perpendicular plane. An x-ray film of the chest was negative except for calcification of the aorta. The cardiac consultant described faint systolic and early, blowing diastolic murmurs at the aortic areas, as well as a presystolic murmur at the apex. An electrocardiogram showed inverted T_1 , T_{CF_1} and T_{CF_2} , and upright T_2 and T_{CF_2} . Left-axis deviation was present, with a PR interval of 0.14 second. The blood Hinton reaction was positive; the blood Wassermann reaction was negative, and the spinal-fluid Hinton and Wassermann tests were positive; the gold-sol curve was 442210000. The precordial pain cleared spontaneously, and the patient was discharged on the fourth day to the Out Patient Department, where he was given four 0.2-gm intramuscular doses of bismuth at weekly intervals for a month. The facial palsy appeared worse at the end of this time, and severe attacks of nocturnal dyspnea and non-radiating precordial oppression suddenly began. Later the patient became dyspneic and orthopneic during the day. A week before admission, after three weeks of severe dyspnea, the voice became hoarse.

On examination the patient was orthopneic and hoarse. There was a blowing, Grade III diastolic murmur in the aortic area and down the left sternal border and a Grade II diastolic mitral murmur. There were dullness, decreased breath sounds and sticky rales at both bases, more on the left than on

the right. The liver edge extended 5 cm below the costal margin. There was slight pitting edema of the ankles. The pupils were fixed to light but reacted to accommodation. A facial paralysis was present.

The temperature was 100°F, the pulse 100, and the respirations 21. The blood pressure was 125 systolic, 25 diastolic.

Examination of the blood showed a red-cell count of 5,170,000, with 12.9 gm of hemoglobin per 100 cc, and a white-cell count of 10,400, with a normal differential. The urine was normal.

In the hospital the patient was restless and dyspneic and complained of substernal burning. On the morning after admission he became extremely restless and then manic, he clutched wildly at his chest, complained of precordial pain and died in a few minutes.

DIFFERENTIAL DIAGNOSIS

DR EDWARD F BLAND The first and foremost feature of this case is syphilis. The initial infection began twenty-nine years before the final disintegration. The early treatment was inadequate by present standards, and in due course the patient appears to have developed active neurosyphilis and almost certainly fatal cardiovascular syphilis. The first clinical feature of some interest is centered around the possibility of neurosyphilis. In addition to the positive serologic findings and abnormal gold-sol curve, he had typical Argyll-Robertson pupils. Furthermore, the spinal-fluid Wassermann reaction was positive. In this connection, one would like to know the spinal-fluid cell count and the protein content, as well as the state of the peripheral reflexes.

DR TRACY B MALLORY The total protein was 24 mg per 100 cc. There is no record of the cell count.

DR BLAND That does not help much. I expected that it might be elevated. Nevertheless, in view of the shooting pain three years before entry and the abnormal findings in the spinal fluid, I suspect that the patient had active late neurosyphilis.

How are we to interpret the seventh-nerve palsy? Isolated seventh-nerve palsy is rarely due to syphilis. In this case I attribute it to peripheral neuritis following exposure to cold.

Then, we come to his admission to the Emergency Ward, which followed the sudden onset of precordial pain that radiated to the left shoulder for four days, and the raising of bloody sputum. We do not know whether there was fever, what was heard in the lungs, or whether breathing was painful. We are told simply that the patient had pain, which was presumably imperfectly relieved by morphine. What could this have been? A pulmonary infarct, of course, is the first thing that comes to mind. The radiation of the pain is consistent, but it would

be helpful to know some of the other clinical details mentioned above.

To what else could it have been due? A coronary occlusion? The electrocardiogram is consistent with that diagnosis. It could also have been due to uncomplicated acute pulmonary congestion from left ventricular failure, or to congestion behind a marked mitral stenosis. It could also have been due to an infection or an expanding (or leaking) aneurysm. I favor pulmonary infarction as the most probable explanation for this illness. Furthermore, I should like to know what the blood pressure was at that time, in view of the abnormal blood-pressure determination recorded a month later. The electrocardiogram was definitely abnormal.

DR MALLORY The blood pressure was 120 systolic, 20 diastolic.

DR BLAND That is a wide pulse pressure and not significantly different from that on the second admission. Therefore, the patient had free aortic regurgitation in spite of the uncertainty about the murmurs. This illness with pain and hemoptysis must not have been taken too seriously, because he remained only four days in the hospital.

Then we come to the physical signs, which were largely limited to the heart. He had a wide pulse pressure, and one observer thought that he had aortic regurgitation. In addition, the characteristic murmur of mitral stenosis was described. That can be present in the absence of mitral stenosis if there is marked dilatation of the heart secondary to free aortic regurgitation. As the murmur is described, however, one must seriously consider the possibility of rheumatic mitral-valve involvement. The electrocardiogram was abnormal but not diagnostic and not particularly suggestive of a recent myocardial infarct. The abnormal findings could have been due to left ventricular strain in the presence of the wide pulse pressure and the evidence of aortic regurgitation. This explanation seems most probable, with perhaps the added effect of constricted coronary ostia. There was not a later tracing by any chance?

DR MALLORY No. Since the first admission was simply to the Emergency Ward, there was no complete workup.

DR BLAND The patient did fairly well. He went home and had four injections of bismuth. Thereafter he rapidly became worse and in the course of a month returned in a serious state, with acute and rapidly progressive heart failure. Until I knew what the blood pressure was at the first admission, — it was not referred to in the original record, — I was inclined to put some emphasis on the apparently striking increase in the aortic regurgitation within a month. The question is, Did the treatment do him any harm? He had had no penicillin. He had had no arsenic. These are the two drugs whose administration might seriously be questioned in the

presence of advanced cardiovascular syphilis with heart failure. Bismuth does not ordinarily cause a Jarisch-Herxheimer reaction by rapid resolution of syphilitic inflammatory tissue. It can cause slow resolution of a gumma, but we have no reason to think that this man had gummatous lesions. At this point we would like to examine the x-ray films.

DR. JAMES R. LINGLEY: I am sorry. The x-ray films have been destroyed.

DR. BLAND: I should have liked to know whether the calcification was limited to the first portion of the aorta. The roentgenologists repeatedly call our attention to the fact that this finding is an important clue to the presence of syphilitic aortitis. Is that correct, Dr. Lingley?

DR. LINGLEY: Yes.

DR. BLAND: I should also have liked to know the size of the aorta and of the heart. Presumably both were dilated. The terminal rapid disintegration and heart failure is further evidence consistent with cardiovascular syphilis. Therefore, I cannot seriously consider any other diagnosis. I could discuss at length the various details of what may have happened at the end. I shall conclude, however, that the patient had neurosyphilis, which was late and possibly active, and that he had cardiovascular syphilis, aortitis and free aortic regurgitation. It is likely that the coronary ostia were constricted by the syphilitic process. I am bothered by the apical diastolic murmur, which, as described in the record, is characteristic of mitral stenosis. The patient died primarily of congestive heart failure.

CLINICAL DIAGNOSES

Syphilitic aortitis
Aortic regurgitation
Myocardial infarction

DR. BLAND'S DIAGNOSES

Cardiovascular syphilis, with aortitis and aortic regurgitation
Congestive heart failure
Neurosyphilis, late, active
Mitral stenosis?

ANATOMICAL DIAGNOSES

Syphilitic aortitis, with aortic insufficiency
Cardiac hypertrophy and dilatation, predominantly of left side
Infarct of heart
Pulmonary edema, massive
Hydrothorax
Pulmonary tuberculosis

PATHOLOGICAL DISCUSSION

DR. MALLORY: The autopsy on this man showed characteristic syphilitic heart disease. The valvular involvement was limited to the aorta. The cusps were separated at the commissures for a distance of 3 or 4 mm. The individual cusps were

thickened, sclerosed and contracted. The aorta was markedly sclerotic, diffusely dilated, wrinkled and scarred in spots between the atheromatous plaques. The entire process was most marked in the thoracic portion of the aorta, diminishing as one proceeded toward the abdominal portion, which is characteristic of syphilis and in contrast to ordinary arteriosclerosis. The coronary ostia, especially that of the left coronary artery, were definitely narrowed by the aortic process. Beyond their mouths they were relatively free from atheroma, nevertheless, there was a large area of scarring at the base of the left ventricle, where the muscle was thinned to a width of only 3 mm. The gross appearance was quite consistent with an ordinary cardiac infarct. There was nothing in the microscopic sections to make one change that diagnosis — nothing, for instance, to suggest a gumma of the myocardium, which is occasionally seen. The lungs showed extensive tuberculous scars at both apices surrounded by focal emphysema, a marked grade of chronic passive congestion and acute terminal pulmonary edema. They weighed over 2200 gm. at the time of autopsy and exuded turbid fluid on the slightest pressure. I cannot give the answer about the central-nervous-system involvement. We did not have permission to examine the brain, and the small section of the cord that was removed by the anterior approach did not show anything. I do not believe that that rules out the possibility of tabes.

CASE 32442

PRESENTATION OF CASE

A fifty-six-year-old woman entered the hospital because of a lump under the left breast.

The patient was apparently well until two years before entry, when she first noticed a small nontender swelling on the chest wall below the lateral portion of the left breast. This swelling increased slowly at first but more rapidly during the following year. It was never painful or inflamed, but several weeks before entry, the patient began to have occasional twinges of pain posterior to the mass.

The patient had had the usual diseases of childhood. Fifteen years before entry she had had typhoid fever, which cleared after four weeks without complications. Four years before entry the urine was reported to contain albumin. Three and a half years before entry she passed about 25 cc of bright-red blood by rectum, a similar episode occurred two weeks before entry. A year before entry she had an attack of bronchitis requiring bed rest for a week. Six months later, the patient noticed slight exertional dyspnea and occasional episodes of tachycardia, but there was no orthopnea, ankle edema, cough or chest pain. During this period she also had frequency and nocturia (five or six times). There had been no recent weight loss.

The patient's mother, sister and brother had died of tuberculosis, and the patient had attended her brother during his final illness twenty years before entry

Physical examination showed an obese woman in no distress. Over the chest wall anteriorly beneath the left breast, a hard, rounded mass measuring 4 by 6 cm was firmly attached to the eighth and ninth ribs and moved with them. It had no connection with the breast. Firm pressure over the mass caused a "drawing sensation," with a slight ache radiating back along the ribs. The breasts were normal. The lungs were clear. The heart was normal except for a Grade I systolic murmur at the apex.

The temperature, pulse and respirations were normal. The blood pressure was 210 systolic, 110 diastolic.

The white-cell count was 5500, and the hemoglobin 12.5 gm. The total protein was 7.5 gm., and the fasting blood sugar 84 mg. per 100 cc. A blood Hinton test was positive. Examination of the urine was negative.

An x-ray film of the chest showed a 6-cm. soft-tissue mass overlying the anterior extremity of the left eighth rib. There was some bone destruction and thickening of the periosteum along the inner margin. The lungs were clear. An electrocardiogram was consistent with coronary disease.

On the seventh hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR RICHARD H. WALLACE: It is unusual in a case of this sort — a tumor of the chest wall — to have so many hints in the history that might lead to a diagnosis.

I believe that the hypertension and heart disease had nothing to do with the mass in the chest wall. The patient had typhoid fever fifteen years before admission. It is possible, many years after typhoid fever, to have a rib infection from the typhoid bacillus, although a lesion of that sort is apt to be tender and is not likely to cause a tumor of this size and consistence. The second point is that on two occasions blood was passed by rectum, suggesting that three years previously the patient had had a primary cancer of the intestinal tract. But there is no further mention of the passage of blood, and no rectal examination, proctoscopic examination or barium study was done, so that the incident was presumably considered irrelevant.

The patient had had bronchitis and had certainly been exposed to tuberculosis, since her mother, brother and sister had died of it, and it is stated that she had taken care of her brother in his final illness, so that tuberculosis should be considered.

The statement that the blood Hinton reaction was positive immediately makes one think of gumma, which is not rare in the chest wall. It usually occurs,

however, along the border of the sternum. Perhaps the x-ray films will be helpful.

DR JAMES R. LINGLEY: This film gives an excellent view of the mass, which extends well out into the soft tissues, but there is no edema of the overlying soft tissues. The mass is smooth and sharply defined, with destruction of the anterior portion of the rib at the costochondral junction. There is also slight expansion and some new-bone formation.

DR WALLACE: Would you say that the tumor probably had its origin in the rib or in the soft parts?

DR LINGLEY: I think that the expansion of the rib is in favor of the former location.

DR WALLACE: There is nothing to suggest inflammation or osteomyelitis. Tuberculosis, of course, must be considered. The chest plate was negative, so that there was apparently no active pulmonary disease. The costochondral margin is a fairly frequent site for tuberculosis. I believe, however, that it is extremely unlikely in this case. Although the tumor did not have the appearance of a gumma, it certainly could have been, and I do not believe that we can definitely rule out such a diagnosis.

We therefore have the possibility of tumors, benign or malignant, that have their origin in bone. In considering the various cells from which such tumors arise, on the marrow side these cells may give rise to myeloma, which is usually multiple, of course, and with this duration extremely unlikely to be still localized. In addition, myeloma shows marked bone destruction, and one would not expect a sizable soft-part tumor. The reticuloendothelial cells presumably give rise to a Ewing tumor, which is also primarily a destructive lesion and could hardly cause a large, hard, soft-part tumor with so little destruction in the rib. The cartilage cells might result in either a chondroma or a chondrosarcoma. This lesion is at the costochondral junction, but it does not have the multilocular appearance or the marked expansion that is ordinarily seen with cartilaginous tumors. The osteoblasts, of course, give rise to osteoma, but in that situation one would not expect destruction. Could this have been osteogenic sarcoma? I think that it is extremely unlikely. The patient, who was over fifty years old, was not in the proper age group, and it is extremely rare to have osteogenic sarcoma in the rib — most of these tumors occur in the ends of the long bones. Could this have arisen from the osteoclastic cells, thus producing a giant-cell tumor? It had none of the characteristics of a giant-cell tumor on x-ray examination. Lymphoma must always be considered, and in the chest wall reticulum-cell sarcoma especially has to be thought of. I cannot rule it out. Many of the rarer tumors, such as the hemangioma, the eosinophilic granuloma and the plasma-cell tumor, should also be mentioned.

Could this have been a metastatic tumor? We have no lead for the site of the primary tumor, and

tastatic lesions are ordinarily punched out, such a large, soft-part tumor is unusual, although it is occasionally seen following carcinoma of the breast. The breast had not been entirely normal, I think. I might seriously consider that diagnosis. On the other hand, about once a year we see metastatic tumor from carcinoma of the breast in which the breasts are completely normal to palpation, and I call one or two cases in which the pathologist had difficulty in finding the minute primary tumor that had given rise to widespread metastases.

The question then comes up whether this tumor originated outside the rib. This seems unlikely because of the x-ray findings.

I neglected to mention another definite possibility—a periosteal fibrosarcoma originating near the edge of the rib and involving it secondarily.

One other extremely rare tumor that is practically never seen is a myoblastoma. This ordinarily has its origin in the tongue in about half the reported cases, but it can occur anywhere in striated muscle. At Pondville Hospital we recently had 2 cases. One had its origin in the deltoid muscle, and the other in the muscles in the palm of the hand. In both cases the tumor was removed locally, and both patients died within eighteen months from widespread osseous metastases without local recurrence. The decision about the nature of the tumor is a matter of speculation, and it finally becomes necessary to do either a biopsy or an excision of the tumor before the real diagnosis becomes evident. But in this particular case I do not believe that tuberculosis or gumma can be ruled out. My first guess, and it is only a guess, is reticulum-cell sarcoma, and the second, fibrosarcoma, probably periosteal in origin.

DR. TRACY B. MALLORY: Dr. Lingley, would you care to make a diagnosis on the x-ray findings alone?

DR. LINGLEY: As Dr. Wallace says, it is a guess, and we can tell definitely only on pathological examination. In this case the point of origin was somewhat in favor of a cartilaginous tumor. I would put chondrosarcoma as my first choice.

CLINICAL DIAGNOSIS

Chondroma of rib

DR. WALLACE'S DIAGNOSIS

Reticulum-cell sarcoma of rib

ANATOMICAL DIAGNOSIS

Chondroma of eighth costal cartilage

PATHOLOGICAL DISCUSSION

DR. MALLORY: Dr. Herrera, will you describe the operative findings?

DR. RODOLFO E. HERRERA: We certainly did not believe that we could rule out a malignant lesion and for that reason decided on radical surgery, which was done at the first opportunity, with the danger of recurrence in mind. We knew that rib tumors have been known to spread through the marrow and to recur at different parts of the rib. Consequently, the chest was entered through the seventh intercostal space, and the tumor was explored from within the pleural cavity. It seemed to arise from the costochondral junction. The seventh and eighth interspaces were occupied by the tumor, and segments of the seventh and ninth ribs were removed by block excision and the eighth rib in toto, with part of the costal arch.

DR. MALLORY: The resected specimen showed a large cartilaginous tumor that evidently arose from the rib cartilage. As in most of these tumors, it looked essentially benign from the histologic point of view. We know, however, that these tumors must be treated with a good deal of caution. We have had one case, which Dr. Herrera mentioned, in which there was extension backward for a considerable distance through the rib. On the other hand, that was a single case. To my mind, the great danger in a case of this type is that certain cartilaginous tumors, in particular those in the rib and symphysis pubis, implant with the most extraordinary facility. It seems as if one tumor cell dropped in the wound almost inevitably grows and is followed by recurrence. We have had a number of such cases. In one, local resection was done, recurrence developed, the parietal pleura was removed, recurrence again developed on the visceral pleura, then some cells dropped down on the surface of the diaphragm, the diaphragm was resected and so on. In spite of the histologically benign appearance and the slight probability of metastases, these are cases that should be radically excised at the first operation, as was done in this case.

SUBSCRIPTION TERMS \$6.00 per year in advance, postage paid, for the United States (medical students, \$3.50 per year), Canada, \$7.04 per year (Boston funds), \$8.52 per year for all foreign countries belonging to the Postal Union.

MATERIAL should be received not later than noon on Thursday, two weeks before date of publication.

THE JOURNAL does not hold itself responsible for statements made by any contributor.

COMMUNICATIONS should be addressed to the *New England Journal of Medicine*, 8 Fenway Boston 15, Massachusetts.

GREATER BOSTON COMMUNITY FUND

THE Greater Boston Community Fund will conduct its campaign for funds to support its Red Feather Services during the first part of November. The Physicians' Division will solicit during the period October 28 to November 15, its quota being \$23,000. The organization of the division is as follows: group chairman, Dr. John P. Monks; group vice-chairmen, Drs. Richard Stetson and George Sturgis; group committeemen, Drs. Archie Abrams, Myles Baker, Marshall Bartlett, Eugene Eppinger, Robert Joplin, Helen Pittman, Vernon Williams, Arthur Pier, Thomas Quigley, Gordon Donaldson, T. Cannon Eley, Paul Chandler, Charles Shedd, Walter Garrey and

Benjamin Tenney. In addition, some ninety physicians will act as solicitors.

Everyone is well aware of the time and effort that many physicians are constantly giving without recompense to charitable institutions. On the other hand, contributions to the Fund represent their support as citizens of the hospitals and social agencies of this community. The drive is a vivid example of a democracy working at its best.

THE OUTLOOK FOR INFLUENZA

IN a recent paper the Commission on Acute Respiratory Diseases¹ formulated a theory concerning the periodicity of influenza. It is based on published data concerning excess annual death rates from influenza and pneumonia since 1920 and on more precise information concerning the occurrence of epidemics of influenza A and B since 1932.

According to these workers, the sixteen widespread epidemics of influenza that occurred in the United States between 1920 and 1944 can be accounted for on the basis of two specific recurrent infections. Influenza A appears to have a cycle of two or three years, and influenza B a cycle of four to six years. They claim that no other influenza viruses have caused *widespread* epidemics in this country during the past twenty-five years. On the basis of this formulation, the probability of occurrence of future epidemics has been forecast within certain time limits, although exact predictions are not possible.

Specifically, the experience with the presumptive epidemics of influenza B is limited because the cycle is longer than that with influenza A and only a small number of past observations are reliable. The theory offered by the commission called for a widespread epidemic before the summer of 1946. At the time when the paper was written, there had been numerous small outbreaks of this infection that might have represented a return of influenza B five years after the previous epidemic, and there was insufficient evidence to indicate that this disease had caused an epidemic in a true sense. Only slight increases in the gross admission rates for respiratory diseases had occurred in the whole United States Army in the continental United States, although small outbreaks of influenza B occurred in certain

uts An influenza epidemic, however, occurred ward the end of 1945 that was roughly comparable in extent to the epidemic of influenza A that occurred in December, 1943.² For the country as a whole a rise in the occurrence of influenza began about the middle of November and reached peak during the week ending December 22, with definite falling off in the next two weeks. This epidemic, which involved nearly all geographic areas of the United States and also occurred in other countries, was definitely identified as being due to influenza B in all areas.

It was found that in the past twenty-seven years, even of the eleven epidemics of presumptive influenza A occurred at an interval of two years and that the remaining four had a three-year interval. On the basis of that experience, there was more than an even chance that influenza A would reappear during the winter of 1945-1946. If influenza failed to occur in that season, the probability that it would appear in the following winter was even greater.

Influenza A was identified in isolated cases during and after the epidemic of influenza B that occurred last December. Small isolated outbreaks were recognized, but no definite epidemic of influenza A occurred. If the theory proposed by the commission is correct, the occurrence of an epidemic of influenza A during the coming fall and winter is almost a certainty. Since the recognized epidemics of influenza A and B in New England have occurred during December or January, an epidemic of influenza A may be expected during those months.

The etiology of the great pandemic of 1918 is not known. Predictions regarding the future occurrence of such a pandemic, if it was caused by an agent other than the virus of influenza A or B, cannot, therefore, be made at the present time.

Considerable information has been accumulated in recent years concerning preventive vaccines against influenza-virus infections, and the subject matter has been given considerable publicity both in the lay press and in the literature distributed by pharmaceutical firms. Physicians will have considerable difficulty in deciding whether or not such a vaccine should be given to any individual or

group. In arriving at a decision, the known facts concerning the available vaccines, their efficacy and the untoward effects to be expected should be taken into consideration.

The influenza vaccines now available are prepared from fertile hens' eggs. After a stated period of incubation the eggs are inoculated with living influenza virus, which is then allowed to grow in the eggs—usually for two days. The allantoic fluid from these embryonated eggs is then harvested, and the virus contained in this fluid is concentrated by one of a number of methods and subsequently inactivated either by formalin or by other means, a preservative being added. The present vaccines usually contain about equal quantities of influenza A and B viruses, together with a certain amount of egg protein.

Influenza vaccines are now being marketed by several of the leading manufacturers of biologicals in this country. Their products are recommended for subcutaneous injection. The dose is a single injection of 1 cc for adults, and two doses of 0.5 cc each given a week apart are recommended for children. For batches of vaccine that produce excessive local or systemic reactions, the dose recommended for children should be used in adults as well.

The optimum protection to be expected from this vaccine, which is achieved about two weeks after the first injection, corresponds to the time of the maximum rise of antibody. Little if any protection may be expected within the first week after vaccination. The protection lasts at least three or four months and probably as long as a year or more. Its efficacy in protecting against both influenza A and B has already been fairly well established. The first opportunity to prove the effectiveness of these vaccines in the prevention of influenza B occurred last year. The reports indicate that influenza B was about ten times as frequent in unvaccinated persons as in those who were protected by the vaccine given in the manner suggested.³ The results in influenza A as observed during the epidemic of 1943-1944 were not quite so good but point to a considerable degree of protection from the vaccine.⁴ Generally speaking, the incidence of influenza in unvaccinated persons was two to six times, averaging about three times, as great as that in vaccinated

persons of comparable groups. The observations at that time were not all done under the most favorable conditions, and some were undertaken within too brief a period before the peak of the epidemic. Better results can probably be expected with the vaccines presently available if they are used under more favorable conditions and at a sufficient interval prior to the expected occurrence of an epidemic.

Reactions to the vaccine are of two types. One is related to sensitivity to egg protein and may be anything from mild urticaria to severe anaphylactic shock. The sensitization of persons so that they later develop allergic reactions from the injection of vaccine containing egg protein or from the ingestion of egg protein is a possibility, although sensitization of the latter type is probably rare. The second type of reaction is one related to the virus content of the vaccine. Symptoms simulating those of influenza may occur but are usually mild, of short duration and not incapacitating. They attest the efficacy of the virus and, when they occur, offer the best evidence that protection will be afforded. These reactions vary considerably with different batches of vaccine and are more frequent when the full dose is given in a single injection.

It should be borne in mind that the common cold and its complications are not prevented by the use of influenza vaccines, nor is protection afforded against bacterial infections such as streptococcal sore throat or against virus infections other than those caused by influenza.

In general, vaccination against influenza, if undertaken, should be done in the New England area during November or immediately on the first occurrence of typical cases of this disease. In the latter event, less protection may be afforded and those already exposed or who come in contact with the infection soon after inoculation may obtain no protection. Vaccination against influenza is not recommended in allergic persons unless there are special reasons for protecting them and unless it is known that they are not specifically sensitive to egg protein. Skin tests with diluted vaccine may be employed to test for such a sensitivity if vaccination is contemplated. Case histories should be obtained concerning sensitivity to egg protein and also concerning previous vaccination with materials that might contain egg protein. Vaccines against

influenza, yellow fever and typhus fever were widely employed, particularly the last, among the armed forces that operated in North Africa and in the Mediterranean Theater, and all of them contained egg protein.

Vaccination is desirable in persons who have previously had severe experiences with influenza and its complications. It may also be recommended for those who are prone to recurrent attacks of upper or lower respiratory-tract infections that persist for a long time after attacks of influenza or the common cold. Large-scale immunization against influenza is recommended among groups in which it is important to minimize the occurrence of absenteeism during the period when epidemic influenza is likely to occur. In department stores, for example, the largest volume of business is transacted in the season when influenza epidemics usually occur. Certain industries that are geared to maximum production at these times might also be hard hit by an epidemic of influenza. In colleges and technical schools, particularly now that they have accelerated programs and much overcrowding, the occurrence of influenza might put the programs entirely out of gear. Under such conditions, large-scale vaccination may be highly desirable, but care should be taken to avoid the inclusion of persons in whom reactions might prove serious.

ENDOMETRIOSIS*

Two Hundred Cases Considered from the Viewpoint of the Practitioner

JOHN FALLON, M.D.,† JAMES T. BROSNAN, M.D.,‡ AND WILLIAM G. MORAN, M.D.§

WORCESTER, MASSACHUSETTS

ENDOMETRIOSIS is a frequent, not a rare, disease. In a recent test period, controlled to the extent that during it all the clinic's operations were done by one operator, there were among the female patients 78 cases of acute appendicitis and 107 cases of microscopically verified endometriosis.

The natural course of this disease is from various stages of severe pain through dyspareunia and sterility, with all the marital disharmonies attendant on those complications, to pelvic invalidism. Endometriosis, however, is one of the few diseases with proportionately serious results for which there is a specific treatment—castration. Less radical therapy is effective if the diagnosis is made even moderately early.

Unfortunately the diagnosis is oftener missed than made. Of the last 200 patients in this clinic with external endometriosis,—to which this paper is limited,—most of whom had previously been examined by one or more physicians and several of whom had been explored, only 6 entered with a diagnosis of endometriosis. No other disease of comparable frequency and severity has had, in our own experience, so low a diagnostic index. Yet the means of diagnosis are at hand. Endometriosis has a cardinal symptom, a pathognomonic sign and an unmistakable gross appearance. Also, it occurs in a sharply limited group of the population.

The missed diagnosis is not a phenomenon peculiar to New England. Nor is it the fault of the practitioner. Despite the excellent reports on endometriosis, we have found no definite description of what we believe to be its fundamental clinical syndrome. Furthermore, there is a widespread assumption that the condition is the private property of the gynecologist. This is unfortunate because endometriosis, like pregnancy, is encountered by all physicians.

PATHOLOGY

External endometriosis is a growth of endometrium anywhere except where it belongs, in the lining of the uterine cavity, the word "growth" should be emphasized. Endometriosis closely resembles cancer. The cells are more differentiated, but it has the clinical attributes of cancer—speedy growth, spread, invasion and metastasis. Cytologically it is benign, otherwise it is cancer, but a cancer against which there is a specific treatment.

This growth, being endometrium, menstruates. The usual structural unit is an endometrial-walled cyst that menstruates into its own lumen. When the menstrual fluid meets peritoneum, it causes local chemical peritonitis. The cyst wall itself, growing centrifugally, invades the host. Invasion is opposed by growth of fibrous tissue varying in degree with the host.

When the growth occurs in an ovary there is least fibrous counterattack, the cyst enlarges rapidly and tends to perforate because it presumably becomes distended with each period. Blowout can occur, usually immediately before or early in menstruation, and produces a syndrome varying in intensity from that of mild appendicitis to that of ruptured tubal pregnancy. Seepage, as opposed to blowout, for the most part causes only an unusually painful period. Seeping menstrual fluid plasters the ovary first to the broad ligament and later to any contiguous area, with characteristic dense, cancerlike adhesions. Month after month, swellings, new seepages and new adhesions build up the so-called "chocolate cyst" of the usual illustration. It is unfortunate that so advanced a stage is the trademark of the disease. Earlier lesions are recognizable (Fig 1).

In addition to the ovary, the pelvic peritoneum, visceral or parietal, is invaded either directly or by the droppings from an ovarian endometrioma. Here the lesion eventually becomes a so-called "blueberry spot" (Figs 2 and 3).

*From the Fallon Clinic.
†Surgeon, Fallon Clinic.
‡Internist, Fallon Clinic.
§Pathologist, Fallon Clinic.

The blueberry spot ordinarily does not exceed a few millimeters, but the surrounding fibrosis may be 1 or 2 cm in diameter. The fibrosis spreads both in the host tissue and, through adhesion, to adjacent tissues. Octopuslike tentacles of endometrial tissue invade the fibrosis, and the lesion shows radiating stellate lines of contraction as if pulling neighboring tissues toward itself.

Figure 3, which shows endometriotic adhesions compared with those of chronic pelvic inflammation, demonstrates the difference between the thin, sheet-like, stretching adhesions of old inflammatory disease and the solid, stellate, puckering tentacles of active endometriosis. The adhesion of the inflammation, a protective mechanism whose work is done, yields to environment and weakens and stretches. The new growth invades the environs, clawing them to itself.

Blueberry spots tend to occur in groups, to coalesce and, with their fibrosis, to build up the cancerlike nodules that are the pathognomonic sign of endometriosis. Such conglomerate tumors cause extensive distortion or, in the sigmoid, stricture.

The densely adherent tumors and the intestinal involvement of late endometriosis may cause unusual difficulty for the surgeon and consequent danger for the patient. Despite the fact that all endometriosis, with the possible exception of that in more advanced sigmoidal strictures,¹ regresses after removal of the ovaries, merely reaching the ovaries to remove them may be dangerously difficult. It is fair to say that endometriosis is a disease that progresses at variable rates but in the direction of death until arrested by the menopause.

We have begun to recognize what we believe to be earlier forms of endometriosis than any of those described above. There are also less frequent forms, such as endosalpingiosis² and the debatable lesions described by Goodall,³ all of which are beyond the scope of this paper.

Endometriosis may appear in the appendix, appendix stumps, laparotomy scars, the cervix, the bladder mucosa, the vaginal wall, along the ureter, hernial sacs, the groin, the vulva, the umbilicus, the small intestine, the abdominal and mediastinal lymph nodes and probably the lung, biceps muscle and forearm.

Internal endometriosis (adenomyosis, adenomyoma) is probably a different disease.

DIAGNOSIS

Endometriosis tends to occur in childless women, in whom pelvic symptoms are likely to be ascribed to neurosis. The variety of places in which lesions occur and the triple action of the disease (as neoplasm, chemical irritant and presumptive hormone manufacturer) make almost any symptom possible. Also, endometriosis often accompanies other symptom-producing pelvic diseases, especially fibroids. A basic syndrome, however, can probably be identified

in spite of all the adventitious symptoms. The picture has three parts: a cardinal symptom, a pathognomonic sign and a specialized susceptibility.

Cardinal Symptom

In our experience increasing dysmenorrhea is almost always present, provided the disease causes any symptoms. One hesitates to call the pain dysmenorrhea, which suggests cramps. This pain may be a cramp but it may also be an ache in the left lower quadrant, an acute stab near the appendix, a soreness in the rectum or a discomfort in the back. It may be sharply localized, or it may radiate to the sacrum or thigh. The nature and location of the pain are not important. What is significant is its relation to menstruation. This relation may vary usually, the pain and the period are synchronous, but occasionally the pain precedes or follows the period, in 1 patient the pain accompanied ovulation rather than flow.

Of course, many lesions cause dysmenorrhea. The criterion of endometriotic pain is *increase*. Increasing dysmenorrhea is not the same as acquired dysmenorrhea. The pain of endometriosis may be acquired — that is, it may start after previously painless periods. Or it may be an increase of existing pain. In either event the increase continues and cumulates. Eventually pains meet across the month, and there is no longer intermenstrual remission but only menstrual exacerbation. Contrariwise, the pain of old pelvic inflammation may decrease at menstruation, possibly from hyperemia.

The severity of the pain is no index of the extent of the lesion. One of the puzzles of the disease is the patient with severe pain but slight lesion, or vice versa. By and large, the pain is more consistent with peritoneal lesions than with those limited to the ovaries. The likeliest to escape diagnosis is the endometrioma, that slowly builds up within an ovary, without seepage and without peritoneal implant, and bursts without warning. One should be wary of appendicitis that occurs on the day preceding menstruation.

What proportion of patients who have increasing dysmenorrhea do not have endometriosis? Unfortunately the clinic lacks a symptom index, so that the answer cannot be given in numbers. Our impression is that the fraction is small.

The history of increasing dysmenorrhea probably bears some relation to the pessimism of many authors about diagnosis. Although appraised as the chief and characteristic symptom of the disease as early as 1929 by King and Fiddes,⁴ its significance has remained relatively unrecognized. In two hundred articles reviewed, increasing dysmenorrhea was emphasized in twelve, mentioned passingly as one of the possible symptoms in seventeen and omitted altogether in the remainder. Before we appreciated this symptom only 20 per cent of our cases were diagnosed before operation, at present

FIGURE 1 Photograph of Ovary (x 1)

An early chocolate cyst, 4 mm in diameter illustrates the importance of visual exploration of the pelvis. Cysts less than 1 mm in diameter can be identified — if one looks instead of feels.

FIGURE 2 Photograph of Piece of Excised Pelvic Peritoneum (x 1/4)

This shows, below, a small "blueberry spot" and, above, red roughness.

FIGURE 3 Photograph of Both Inflammatory and Endometriotic Adhesions between an Appendix Epiploicum and the Uterus (x 2)

U is the uterus, A an appendix epiploicum, and S a retracting suture. This illustrates certain differences in appearance and in nature between endometriosis and chronic pelvic inflammation. The inflammatory lesion (I) is thin sheet-like stretching. The adhesion of endometriosis (E) is strong solid contracting, note the typical stellate lines of puckering. "Blueberry spots" appear at B, and the endometriotic nodule at N.

per cent are so diagnosed, and the missed 30 per cent consists principally of patients with painless ovarian endometriomas or with early endometriosis discovered at operation for other disease or of patients who, for one reason or another, were admitted directly to the hospital without passing through the clinic. There are lessons in this last group they were admitted by a member of the house staff, the interview with a member of the clinic was—in war days—brief, and the endometriosis was recognized for the first time at operation.

A change in the time or amount of menstrual flow is also a symptom of endometriosis. Often—and from our experience, we believe, erroneously—it is called the chief symptom. In this series it was present in a third and absent in two thirds of the cases. It is therefore of no diagnostic value. The symptom may help, however, by bringing to the physician patients who recognize irregularity as pathologic but who accept periodic pain as woman's normal lot. In every case of menorrhagia, therefore, inquiry should be made regarding dysmenorrhea.

Jarring of the pelvis, from walking on a hard sidewalk, riding on a rough road, coitus, defecation or even sitting down suddenly, may increase the pain of endometriosis. The absence of this symptom means nothing. Its presence, which connotes some serious pelvic peritoneal irritation, always suggests but is not diagnostic of endometriosis. Like menorrhagia, however, this variation may cause women who accept so-called "normal dysmenorrhea" in silence to consult a physician.

Pathognomonic Sign

Pain on movement of the cervix at vaginal examination has the same pathologic significance as the pain on jarring referred to above—that is, it signifies a serious variety of peritoneal irritation, it is also frequently present but is not pathognomonic. The pathognomonic sign is the hard, fixed, invading nodule of endometriosis. The characteristic feel of this structure is a matter of tactile memory and not to be learned from print, although if one's tactile imagination is active, Figure 3 will suggest how it ought to feel. It is nearest like the feel of cancer metastases, and to the extent that it cannot always be differentiated from these it is not pathognomonic, usually, however, it can be differentiated, and then it is definitive. Certain stratagems are useful in the search for the nodules. Rectal palpation is often more rewarding than vaginal, and combined, simultaneous rectal and vaginal examination is more satisfactory than either alone. The posterior-vault peritoneum and the uterosacral ligaments, on whose anterior reaches many of the nodules occur, can be tensed for better palpation by pushing the cervix forward by the finger or pulling it downward by a tenaculum. Examination midway between periods, followed by re-examination at the

beginning of the next period, may show the nodule to be tenderer on the second occasion.

Unfortunately, nodules large enough to be palpable often indicate advanced disease, and nodules may be present but out of reach. Actually, pelvic examination substantially contributed to diagnosis in a little less than half of our cases in which the diagnosis was made. Despite a pelvis normal to palpation, therefore, the diagnosis should be made from the history alone.

Specialized Susceptibility

The occurrence of endometriosis is largely limited to one group of people. The diagnosis should not be rejected because a patient is outside this group, but the possibility should be considered in every patient within it. This group consists of women who are not having children—the sexually dormant, whether married or single.

It is often said that endometriosis causes sterility. It is true that women with advanced endometriosis are and those with early endometriosis may be sterile. Yet at least 26 cases of coexistent pregnancy and endometriosis have been collected,⁵ and this series adds a probable 10 in 2 cases old endometriosis was shown at operation soon after miscarriage, 1 patient had a ruptured tubal pregnancy and old endometriosis and 7 patients had become pregnant since the estimated onset of the disease. Parenthetically, in these 7 the pregnancies seemed temporarily to have arrested the endometriosis.

That endometriosis causes sterility is true but is not the point. The significant fact is that endometriosis occurs in women of child-bearing age who are not having children. The phrase "child-bearing age" should be clarified. The youngest patient of whom we have found record was a thirteen-year-old girl in this series. There were also 1 girl of sixteen and 7 of seventeen, eighteen or nineteen years of age.⁶ At the other extreme were 3 women of forty-seven to fifty and 1 of fifty-three years of age. All were menstruating, and all, except 2, had been menstruating for at least five years. Shortly after the menopause, endometriosis becomes a relic—3 patients, ranging in age from fifty-three to sixty-six years, had inactive residua of the disease. To analyze the phrase "are not having children" in this series over two thirds of the 200 women had never had a child. This, of course, is significant. Women with children, however, can have endometriosis,—59 of the 200 patients did,—as can the mother of a large family—13 of these mothers had five children or more. The phrase therefore signifies only women who have not had a baby recently—that is, for about five years. In this series there were 14 women who had been pregnant within the five years before discovery of the disease. But 4 of them had artificial endometriosis, caused by operation. In 2 of the 10 patients with spontaneous disease the endometriosis appeared to have started within five years

of delivery. But in each of the other 8 the symptoms of endometriosis, we believed, could be traced back to a fallow period of five years preceding the last pregnancy. In other words, of a total of 190 patients with spontaneous endometriosis — the 10 with artificial disease being subtracted from the total of 200 — the disease seemed to have begun within five years of confinement in only 2 cases.

There is contributory evidence in the thirteen mothers who had five or more children. These women all married young, had their babies early, stopped having babies and, after five years or more, developed endometriosis. Finally, although endometriosis occurs in youth, reports of its appearance before approximately five years of menstrual life are extremely rare.⁶

The most practical item in diagnosis after increasing dysmenorrhea is therefore considered to be a history of about five years of nonpregnancy preceding the disease. And it seems to make no difference whether the nonpregnancy is from inability, indecision or lack of opportunity. Palpable endometriomas confirm the diagnosis but are absent as often as present.

TREATMENT

Endometriosis is a disease for which a true specific treatment is available. Following ovarian deactivation endometriosis gradually regresses, with insignificant residua. But the price — castration — is high. In the hope of avoiding castration in advanced cases, we have begun to study temporary ovarian deactivation by small doses of radium after confirmation of diagnosis by peritoneoscopic biopsy. Masculinizing, follicular and luteinizing hormones have also been suggested, but the last two are probably as likely to harm as to help.

For such a chemical problem the future may offer a chemical solution that will restrict the surgeon to the taking of biopsies. But today he has a procedure that is reasonably efficient and less costly than castration. This consists in diagnosis while all lesions are young enough to be removed individually without castration and in prophylaxis.

The arbitrary five fallow years discussed above may be new, but there is nothing original about the concept of endometriosis as a disease of the sexually dormant.^{7, 8} Meigs⁹ calls it a physiologic response to an abnormally uninterrupted menstrual career. If the theory is sound the prophylactic is obvious — more obstetrics would engender less gynecology. Marriage at the age of seventeen and a child every three years would probably abolish endometriosis. It should be remembered that the disease itself, not eugenics, ethics or even common sense, is under consideration. Marriage at twenty and no five years without a baby would perhaps be more sensible.

An excellent opportunity for prophylaxis is offered the practitioner when he refers to the surgeon a woman with appendicitis. Because of the fre-

quency of endometriosis and of other unsuspected pelvic lesions, we believe that it is often fitting for the practitioner to suggest exploration of the pelvis in addition to removal of the appendix. Digital examination can miss an early lesion. But to the eye endometriosis is as unmistakable as chicken pox, so that no pelvis can be said to have been adequately investigated until it has been explored by vision. This necessitates a median incision which, when routinely used for appendectomy in women, has revealed a surprising amount of endometriosis.

In patients with severe dysmenorrhea, even if the symptom is not increasing, exploration is often indicated when lesser treatment fails. If no endometriosis is found, presacral sympathectomy may justify the operation. Endometriosis, which is frequent and painful, causes sterility; it is therefore sound prophylaxis to be radical about deciding to explore in suspicious cases.

Some experienced operators do not bother to excise small lesions, others allow even large lesions to remain but resect three quarters or more of the ovarian tissue in the hope of diminishing ovarian function. To us, both these procedures seem overconservative, for the following reasons: large endometriomas grow from small ones, patients with small lesions may have a great deal of pain, which ceases after removal of the lesions, subtotal oophorectomy, like subtotal thyroidectomy, is a physiologic compromise, and, finally, in severe cases, we have observed endometriomas that continued to grow after previous operation or the disease itself had destroyed all but a shell of ovarian tissue.

True conservatism, we believe, consists in spending an hour picking nodules out of a pelvis, even though castration could be done in ten minutes. We have set ourselves the alternative of complete extirpation or castration, and have taken pains and accepted risks to excise the disease whenever excision was possible. One of the 2 deaths in this series occurred from operation for endometriosis, the other from hepatic carcinoma metastatic from the colon in a patient whose incidental endometriosis had not been treated. The few exceptions to the rule were in young girls with extensive lesions in whom the treatment consisted in removal of the disease that it was mechanically practicable to remove, combined with temporary castration by small doses of radium. Obviously, the risk of radiating ova that subsequently might become impregnated should be taken only in extreme circumstances.

About half the patients in this series were castrated. To our great disappointment and despite definite improvement in diagnosis and steadily increasing willingness to resect more difficult lesions the proportion of patients castrated is not significantly lessening. Of the first 100 patients in the series, 52, and of the last 100, 45 were castrated.

patients in the series are being followed, but the results of treatment for endometriosis should not be quoted before the menopause. Among the treated patients, recurrence from the use of stilbestrol has been encountered and has so far yielded to withdrawal of the medication. It can be said that radical excision without castration may afford some relief and sometimes results in pregnancy — Payne¹⁰ reported 10 and Haydon⁸ 19 patients who became pregnant following operation, Counseller¹¹ reported ten pregnancies in 7 patients, and 3 of our patients have had one child each.

Recurrence is suspected in 2 of our patients, who are nevertheless being only watched. The 3 patients with recognized recurrences became asymptomatic following irradiation. As Pemberton¹² has pointed out, irradiation is not to be undertaken casually. The dense adhesions of the disease may bind the intestine into a dangerously immobile target for the x-rays.

SUMMARY

Endometriosis is a progressive, painful, sterilizing, crippling disease that can be both prevented and cured. Opportunities for prevention and cure are lost because no accurate clinical picture has become generally accepted and because the frequency of the disease is not appreciated.

In the female patients seen in this clinic the incidence of endometriosis was greater than that of acute appendicitis.

Endometriosis is an antivenereal disease — that is, it is associated with sexual unfulfillment. The prophylaxis seems to be early marriage and a child every few years.

Endometriosis is a new growth of menstruating endometrium that, invading and sometimes metastasizing, tends to spread through the pelvis,

causing chemical peritonitis, dense adhesions, sterility, destruction of ovaries and stricture of the pelvic intestine. Ovarian hormone is necessary to the progress of the disease. The course, which is reversed by ovarian deactivation, may be arrested by excision of the lesions. To arrest without castration necessitates diagnosis before the lesions have become mechanically unresectable.

Contrary to general opinion, clinical diagnosis is usually possible. It depends on ability to separate from a mass of adventitious pelvic symptoms and signs the following basic syndrome of endometriosis: cumulatively increasing pain at the time of the period occurring after about five years of menstruation without pregnancy. Endometriotic nodules are pathognomonic but often not large enough to be felt, in which event the diagnosis should be made on the basis of the history alone.

Because endometriosis can be seen long before it can be felt the practitioner should be as radical about advising surgical exploration as the surgeon is conservative about castration.

BRIGHT'S DISEASE CLINICAL MANIFESTATIONS IN RELATION TO ETIOLOGY AND PROGNOSIS*

RAYMOND D. PRUITT, M.D.

ROCHESTER, MINNESOTA

IN 1827 Bright¹ pointed out the association between dropsy, albuminuria and hardened kidneys. In this simple correlation he established the foundation for a multitude of observations that accumulated in succeeding years under the caption of "Bright's disease." It soon became apparent that, from both a clinical and a pathological standpoint, Bright's disease was not an entity but an assemblage of diseases. Subsequent efforts to achieve specificity resulted in many classifications, some accurate and many detailed. But what is satisfying to an expert in the field is not always expedient for one whose circumstances demand familiarity with the range of clinical medicine. As a result, physicians have frequently resorted to the broad and time-honored diagnosis of Bright's disease rather than attempting to drag out a rarely recognized term buried deep in some current classification of vasculorenal disease.

But Bright's disease is not a satisfying diagnosis. Between excess of generalization and impracticable specificity there should be some compromise. A simple classification of vasculorenal disease from the point of view of a clinician should be one in which the nomenclature is descriptive of clinical findings. It need not become involved with pathological terms such as "small granular kidneys," "large pale kidneys," "primarily and secondarily contracted kidneys" and "flea-bitten kidneys."

FUNDAMENTAL CLINICAL MANIFESTATIONS

The important clinical findings in Bright's disease ("vasculorenal disease") is an equally comprehensive and more descriptive term) are renal insufficiency, dropsy and hypertension. If, in a scheme of diagnosis, importance is to be attached to these clinical manifestations, it is essential that the character of each be understood. For this reason the following elaboration of the nature of each is undertaken.

Renal Insufficiency

It is apparent that one of the most significant effects of disease on the kidney is impairment of functional capacity. The degrees of damage may be described under three headings: latent renal damage, compensated renal insufficiency and uncompensated renal insufficiency.

Latent renal damage. The existence of latent impairment of kidney function is dependent on the

large reserve capacity of the normal organ. Under this heading are included cases in which there is no demonstrable reduction in the functional capacity of the kidney. Responses to all tests are within the normal range. Yet a pathologic process known to affect the kidney exists. An example of this type of renal damage is found in early essential hypertension.

Compensated renal insufficiency. At this stage of renal damage, a sufficient proportion of the functioning elements of the kidney have been damaged or destroyed to eliminate a large measure of the reserve capacity of the organ. So long as the patient is in good general health, the concentration of urea in the blood remains normal. There is a reduction, however, in the capacity of the kidney to do a specific amount of work in a limited time, as demonstrated by the urea-clearance test. The power to produce concentrated or a dilute urine is impaired. With the development of an unusual strain on the organ actual renal insufficiency develops and the concentration of blood urea may rise.

Uncompensated renal insufficiency. With the development of this degree of destruction of kidney substance, not only are the reserves of the organ exhausted but also the capacity to care for the current excretory load is lost. The concentration of urea in the blood is elevated and, unless compensation is restored, mounts steadily. The end result of this sequence is the development of the uremic state. The term "uremia" or "uremic state" may well be reserved to describe that terminal phase of renal insufficiency during which certain overt manifestations of kidney failure develop—namely, somnolence, confusion, nausea, vomiting, muscular irritability and convulsive seizures.

Dropsy

In the absence of cardiac failure, dropsy in a case of chronic renal disease is the outward and visible sign of a derangement in the metabolic processes of the body that has been designated the "nephrotic state." The initial factor in the development of this syndrome is probably the loss of excessive amounts of albumin in the urine. The albuminuria itself is believed to be secondary to increased permeability of the glomerular membranes, permitting the smaller molecules of the normally retained serum proteins to pass into the urine. Secondary to the

*From the Division of Medicine, Mayo Clinic.

loss of serum proteins there develops hypoproteinemia associated with a disturbance in the osmotic equilibria of the blood and tissue fluids, culminating in the accumulation of increased amounts of fluid in the tissue spaces. The hyperlipemia that is also a feature of the nephrotic syndrome is probably a compensatory reaction directed toward restoration of a more nearly normal osmotic relation.

Hypertension

Of the three major clinical manifestations of vasculorenal disease, elevation of the blood pressure is the most frequent. Foregoing for the moment any distinction between angiospastic processes and the more usual sclerosis and narrowing of the arterioles, one may divide the hypertensive reaction of vasculorenal disease into four groups, according to the classification of Keith, Wagener and Barker,² in which certain changes in the ocular fundi are of fundamental importance. The divisions are as follows:

Group 1 Patients who have only mild narrowing or sclerosis of the retinal arterioles fall into this division.

Group 2 Patients are placed in this category if they have moderate to marked sclerosis of the retinal arterioles, whether of the chronic type—characterized especially by exaggeration of the arterial reflex and arteriovenous compression—or of the postangiospastic type—characterized especially by, generalized and localized irregular narrowing of the arterioles.

Group 3 Patients who have retinitis of the angiospastic type—characterized especially by edema, cotton-wool patches and hemorrhages in the retina, superimposed on a combination of sclerotic and spastic lesions in the arterioles—belong to this group.

Group 4. This group comprises patients with measurable edema of the disks in addition to the findings described above.

Although the arteriolar changes are readily studied clinically only in the retina, pathological investigations support the postulate that the arteriolar disease in hypertension is generalized.³⁻⁵ Therefore, in cases of hypertension, an accurate descriptive diagnosis is "diffuse arteriolar disease with hypertension, Group 1, 2, 3 or 4."

ETIOLOGY

Regardless of the nature of the specific disease affecting the vasculorenal system, the major clinical manifestations may be described with reasonable consistency in terms of the triad discussed above. To this proposition there is a corollary: Bright's disease is not an entity but an assemblage of diseases grouped together, not because of similarity of cause

but because of similarity of effect. In the following paragraphs the relation between certain specific causes and the triad of effects is elaborated, Bright's disease being analyzed from the etiologic standpoint whereas the fundamental unity found in the clinical expressions is retained.

Chronic Glomerulonephritis

The term "chronic glomerulonephritis" implies the existence of an earlier phase of the disease that in some cases was acute, almost explosive. The patient so afflicted was obviously ill, with an elevated temperature and labored respirations. The urine contained many casts and erythrocytes and much albumin. Anasarca, hypertension and renal insufficiency may have been present simultaneously in this acute phase.

In contrast, this preliminary stage may have had an insidious onset unattended by symptoms. Its existence could be defined only by examination of the urine, in which there were small amounts of albumin and sometimes a few casts, erythrocytes and pus cells.

Slowly or rapidly, but fortunately not inevitably, chronic glomerulonephritis evolves from the nephritis of acute or insidious onset. The initial lesion was in the glomerulus. As the destructive changes progress in this portion of the nephron, any one or any combination of the three clinical features of vasculorenal disease may develop concurrently or sequentially. Furthermore, although two or all three manifestations may be present, one component may be mild and another severe. Finally, a patient may pass through phases during which, in succession, he suffers primarily from one aspect of the triad, he recovers from this and he succumbs to another expression of the disease.

It is not expedient or essential to clarify to present illustrations of all these potential combinations. Two examples are sufficient. First, a patient with chronic glomerulonephritis and findings pathognomonic of all phases of the triad may present the following: a blood urea concentration of 200 mg per 100 cc (normal 15 to 40 mg), large amounts of albumin in the urine, a value for serum protein of 3.5 gm per 100 cc (normal 6 to 8 gm), with an albumin-globulin ratio of 1.0:1.2 (normal 2.0:1.0), anasarca, and hypertension with associated arteriolar disease. A descriptive diagnosis in such a case is chronic glomerulonephritis with severe renal insufficiency (as indicated by the elevated blood urea level), nephrotic syndrome (as demonstrated by albuminuria, hypoproteinemia, reversal of the normal albumin-globulin ratio and anasarca) and superimposed diffuse arteriolar disease with hypertension.

In contrast is the patient with a relatively pure nephrotic syndrome. Typical findings in such a case are a blood urea value of 32 mg per 100 cc,

BRIGHT'S DISEASE CLINICAL MANIFESTATIONS IN RELATION TO ETIOLOGY AND PROGNOSIS*

RAYMOND D. PRUITT, M.D.

ROCHESTER, MINNESOTA

IN 1827 Bright¹ pointed out the association between dropsy, albuminuria and hardened kidneys. In this simple correlation he established the foundation for a multitude of observations that accumulated in succeeding years under the caption of "Bright's disease." It soon became apparent that, from both a clinical and a pathological standpoint, Bright's disease was not an entity but an assemblage of diseases. Subsequent efforts to achieve specificity resulted in many classifications, some accurate and many detailed. As a result, physicians have frequently resorted to the broad and time-honored diagnosis of Bright's disease rather than attempting to drag out a rarely recognized term buried deep in some current classification of vasculorenal disease.

But Bright's disease is not a satisfying diagnosis. Between excess of generalization and impracticable specificity there should be some compromise. A simple classification of vasculorenal disease from the point of view of a clinician should be one in which the nomenclature is descriptive of clinical findings. It need not become involved with pathological terms such as "small granular kidneys," "large pale kidneys," "primarily and secondarily contracted kidneys" and "flea-bitten kidneys."

FUNDAMENTAL CLINICAL MANIFESTATIONS

The important clinical findings in Bright's disease ("vasculorenal disease" is an equally comprehensive and more descriptive term) are renal insufficiency, dropsy and hypertension. If, in a scheme of diagnosis, importance is to be attached to these clinical manifestations, it is essential that the character of each be understood. For this reason the following elaboration of the nature of each is undertaken.

Renal Insufficiency

It is apparent that one of the most significant effects of disease on the kidney is impairment of functional capacity. The degrees of damage may be described under three headings: latent renal damage, compensated renal insufficiency and uncompensated renal insufficiency.

Latent renal damage. The existence of latent impairment of kidney function is dependent on the

large reserve capacity of the normal organ. Under this heading are included cases in which there is no demonstrable reduction in the functional capacity of the kidney. Responses to all tests are within the normal range. Yet a pathologic process known to affect the kidney exists. An example of this type of renal damage is found in early essential hypertension.

Compensated renal insufficiency. At this stage of renal damage, a sufficient proportion of the functioning elements of the kidney have been damaged or destroyed to eliminate a large measure of the reserve capacity of the organ. So long as the patient is in good general health, the concentration of urea in the blood remains normal. There is a reduction, however, in the capacity of the kidney to do a specific amount of work in a limited time, as demonstrated by the urea-clearance test. The power to produce a concentrated or a dilute urine is impaired. With the development of an unusual strain on the organ, actual renal insufficiency develops and the concentration of blood urea may rise.

Uncompensated renal insufficiency. With the development of this degree of destruction of kidney substance, not only are the reserves of the organ exhausted but also the capacity to care for the current excretory load is lost. The concentration of urea in the blood is elevated and, unless compensation is restored, mounts steadily. The end result of this sequence is the development of the uremic state. The term "uremia" or "uremic state" may well be reserved to describe that terminal phase of renal insufficiency during which certain overt manifestations of kidney failure develop—namely, somnolence, confusion, nausea, vomiting, muscular irritability and convulsive seizures.

Dropsy

In the absence of cardiac failure, dropsy in a case of chronic renal disease is the outward and visible sign of a derangement in the metabolic processes of the body that has been designated the "nephrotic state." The initial factor in the development of this syndrome is probably the loss of excessive amounts of albumin in the urine. The albuminuria itself is believed to be secondary to increased permeability of the glomerular membranes, permitting the smaller molecules of the normally retained serum proteins to pass into the urine. Secondary to the

*From the Division of Medicine, Mayo Clinic.

age in whom the illness has been present for a similar period. Each has renal insufficiency with a blood urea concentration of 150 mg per 100 cc. But one has superimposed diffuse arteriolar disease with hypertension, Group 3, whereas the other has an essentially normal arteriolar system. The prognosis for the latter is much better than that for the former.

Equally significant is the consideration of 2 patients each with a moderately severe nephrotic syndrome. One has normal renal function so far as can be determined by tests, and the other has uncompensated renal insufficiency. All else being equal, the prognosis for the latter is less favorable than that for the former, not only because two pathologic processes are worse than one but also because treatment of one manifestation often entails application of measures unfavorable to the other. The patient with renal insufficiency has lost his ability to produce a concentrated urine. Therefore he must excrete large amounts of urine to avert a rise in the blood urea concentration. But the wisdom and the feasibility of administering large amounts of fluid to the patient with an advanced nephrotic

syndrome constitute problems that evade simple resolution.

* * *

More extended consideration of therapeutic problems in cases of Bright's disease is not appropriate to this limited discussion. If there is value in undertaking the treatment of vasculorenal disease by application of measures directed toward alleviation of renal insufficiency, the nephrotic syndrome or hypertension, that value is apparent in the illustrations elaborated above.

marked albuminuria, a concentration of serum protein of 3.5 gm per 100 cc, with an albumin-globulin ratio of 1:0.12, and generalized anasarca, but with normal blood pressure and no definable narrowing or sclerosis of the retinal arterioles. Such a patient presents evidence indicative of adequate renal function and of a normal arteriolar system without hypertension in the presence of a well developed nephrotic syndrome.

As a concluding observation regarding chronic glomerulonephritis it may be noted that renal insufficiency unattended by hypertension or by the nephrotic syndrome is probably the rarest clinical manifestation of the disease. Such cases occur, however, and a patient may pass into the uremic state and die without the development of either of the other two features of the triad.⁶

Essential Hypertension

Primary consideration was given above to chronic glomerulonephritis because of its basic relation to the three cardinal manifestations of vasculorenal disease. During the course of chronic glomerulonephritis, hypertension may or may not appear and may or may not be a symptom of the disease. But hypertension may also occur as an isolated phenomenon, apparently unrelated either to chronic glomerulonephritis or to any of the other entities affecting the vasculorenal system. In this event, the clinical manifestation becomes the disease and bears a name, albeit an unrevealing one — "essential hypertension." From the standpoint of incidence alone, essential hypertension is the most important entity included under the term "Bright's disease."

Whereas the site of the initial lesion in chronic glomerulonephritis can be identified with precision, the primary change in essential hypertension remains indeterminate. The kidney undoubtedly becomes involved in advanced stages of the disease, but that the primary lesion is renal is far from an established fact. Rather, the initial lesions in essential hypertension appear to be arteriolar and so generalized as to justify the caption "diffuse arteriolar disease."

However different their origins, chronic glomerulonephritis and essential hypertension in their final stages may be confusingly similar. Although the nephrotic syndrome is peculiar to glomerulonephritis, renal insufficiency and hypertension are frequently associated in the terminal stages of both diseases. Whereas marked albuminuria with many casts and erythrocytes is usually indicative of primary glomerulonephritis, all these urinary findings may be duplicated in the terminal stages of severe hypertension. Sometimes the history or the age of the patient supplies evidence helpful in defining the initial lesion. A previous episode of acute glomerulonephritis, a record of albuminuria for years prior to the onset of hypertension and youth of the

patient may suggest that the initial lesion was in the glomeruli. On the other hand, a history of high blood pressure of many years' duration, without other indications of impaired health, is more suggestive of primary hypertensive disease. In some cases it remains for the pathologist to establish whether the primary lesion was arteriolar or glomerular, but the decision is not always achieved with finality even at this ultimate stage.

Other Conditions

A sound knowledge of chronic glomerulonephritis and essential hypertension and their interrelations is fundamental to an understanding of the rarer and often simpler causes of Bright's disease. One of these is chronic pyelonephritis, in which extensive destruction of renal tissue by an infectious process may lead eventually to advanced renal insufficiency with superimposed diffuse arteriolar disease and hypertension. In polycystic disease, destruction of the renal parenchyma is accomplished by a different means but with similar results. Toxic processes may lead to tubular damage and suppression of formation of urine, with consequent acute renal insufficiency usually unassociated with appreciable hypertension or the nephrotic state. Lymphoblastomatous or amyloid infiltrations of the kidney may give rise to a relatively pure nephrotic syndrome later complicated by renal insufficiency. Periarteritis nodosa is sometimes attended by hypertension and ultimately by renal insufficiency. But whatever the pathogenesis of the lesion in the vasculorenal system, the overt expressions of the disease can be related in most cases to one or more of the well established patterns.

PROGNOSIS

In concluding this survey it is reasonable to turn from the consideration of diagnosis and classification to the problems of prognosis and treatment, in which the delineation of the triad of renal insufficiency, nephrotic syndrome and hypertension is also of value. Prognosis is not a precise science and demands calculations more subtle than those of arithmetic. Some insight into the future of the patient with vasculorenal disease can be achieved, however, if it is recognized that the course is dependent on the number of the clinical manifestations that are combined, as well as on the severity of the individual components. This generalization is applicable to the more frequent etiologic processes in vasculorenal disease — namely, chronic glomerulonephritis, essential hypertension and chronic pyelonephritis. The significance of the generalization is minimized in cases in which the primary process is one of the rarer entities, such as lymphoblastoma, amyloid disease or periarteritis nodosa.

In illustration, comparison may be made of chronic glomerulonephritis in 2 patients of similar

abscess is the upper and posterior portion of the right lobe.⁴ Abscesses in this lobe often extend upward and may penetrate the diaphragm and rupture into the lung. It is well known that amebic abscesses occur in many other organs.

Hepatic disease complicating amebiasis usually appears one to three months after an attack of dysentery, but it may manifest itself during an attack or much later. The symptoms of hepatic abscess include pain or discomfort over the liver, with occasional reference to the right shoulder, irregular and intermittent fever, sweats, chills, nausea, vomiting, weakness and loss of weight. Jaundice, except in mild degree, is unusual. Diarrhea or dysentery is present in only about a fourth of the cases of proved liver disease. The diagnosis of hepatic amebiasis depends primarily on a high index of suspicion. Not infrequently a diagnosis of fever of undetermined origin is carried for weeks, because the clinical picture is not specific and the physician does not consider amebiasis as a possible cause of the symptoms. Liver-function studies are not diagnostic, they are merely suggestive and help to point the finger of suspicion at the liver. Leukocytosis of moderate degree is usually present. Stool examination for amebic cysts is, of course, of paramount importance, but is often negative even in the most competent hands. The use of intravenous Diodrast and planography is advocated in attempting to locate a liver abscess. Because of its specificity in amebiasis, emetine constitutes a therapeutic test of great value, but since the drug is a potent protoplasmic poison, it should be used circumspectly.

The following case reports are presented to illustrate the hepatic complications of amebiasis, as well as the extreme difficulty of diagnosis. Because of the obscure nature of the disease it is easy to see how errors in treatment can occur unless one is constantly aware of the possible existence of amebiasis.

CASE 1 R C D, a 35-year-old man, was admitted to the hospital, on October 18, 1945, for the treatment of malaria. The significant fact in the history was service in the Southwest Pacific area, during which he had had malaria and amebic dysentery. Prior to this admission he had suffered from diarrhea and pain in the left upper quadrant of the abdomen, accompanied by chills, fever and sweats.

Physical examination on admission revealed the patient to be acutely ill. The only significant finding was marked tenderness and muscle spasm in the left upper quadrant of the abdomen with no definite splenomegaly. The temperature was 102°F., the pulse 100, and the respirations 22. Examination of the blood showed a red-cell count of $\pm 4,010,000$, with a hemoglobin of 86 per cent (Sahli), and a white-cell count of 13,000, with 81 per cent neutrophils. No malarial parasites were found in the blood smear.

The patient was placed on a regimen of quinacrine, which had no effect on the clinical course—the patient suffered from fever, chills and sweats at irregular periods, with weakness and occasional nausea and vomiting. The tenderness and pain in the left upper quadrant persisted. The red-cell count gradually diminished, and a transfusion of 500 cc of whole blood was given on three occasions. Examination of the stools revealed no amebic cysts or motile forms. Sigmoideoscopic examination was negative. The cephalin-flocculation test was +, and the icterus index was 9 and 3

on two occasions. A gastrointestinal x-ray series was negative. A sense of fullness developed in the epigastrium, together with slight enlargement of the liver. At the same time the patient's sense of well being gradually improved, and the pain in the left upper quadrant of the abdomen slowly subsided. No splenomegaly could definitely be made out at any time.

On November 21 a definite tender mass about the size of a lemon was noted in the left upper abdominal quadrant. Surgical exploration disclosed an encapsulated abscess in the region of the anterior surface of the left lobe of the liver. The abscess was incised freeing "anchovy-paste" pus, drained by suction, packed and irrigated daily with 1:1000 solution of emetine hydrochloride. At the same time 20 mg of emetine hydrochloride was administered intramuscularly three times a day for 7 days.

On November 25, while the patient's condition was slowly improving, he developed a chill, followed by a rise in temperature to 103.4°F. A blood smear revealed the presence of *Plasmodium vivax*. Response to quinacrine hydrochloride was prompt, and convalescence continued uneventfully. The patient made a complete recovery.

In the early stages of the illness the patient's chief complaint was directed entirely toward the left upper quadrant. The consistently negative blood smears and the failure to respond to quinacrine on admission removed malaria from the list of diagnostic possibilities, although this disease had appeared to be the likeliest cause of the chills and fever. Subsequently, intensive studies made to rule out the presence of blood-stream infection and renal suppuration were negative. The possibility of amebiasis had been entertained, but no definite findings were noted. In retrospect, we believe that the use of emetine early in the course of hospitalization would have been of significant diagnostic value, and might conceivably have prevented the formation of a full-blown liver abscess. Despite the failure to find the pathogen in the feces, the pus or the wall of the abscess, it was considered certain, on clinical grounds, that the patient did have an amebic abscess. The pus was characteristically free of pathogens, although they are often found in the wall of the abscess.

CASE 2 W F B, a 27-year-old farmer, had been discharged from the Army on January 20, 1946, shortly after his return from the Southwest Pacific. At the time of discharge he was in good health. He had never been ill during his service in the Army and did not recall any minor episodes of diarrhea or fever. About 3 weeks prior to admission to the hospital he became ill, with fever and pain in the right chest. He consulted his family physician, who treated him for malaria without improvement and who, about 10 days before admission, thought that there was fluid in the right chest. No x-ray film was taken, nor was a thoracentesis performed. On admission the patient complained of mild pain in the lower right chest on deep inspiration, as well as a slight cough without expectoration. There had been no dyspnea. He had lost 15 pounds in the preceding 2 weeks. He had had frequent head colds for several years. Several chest x-ray films taken in the Army had been negative for tuberculosis. He had had no significant illness or operations.

Examination revealed a well developed and well nourished man, who was ambulant and not acutely ill. Significant findings were slight impairment of percussion resonance over the extreme right base of the chest posteriorly, distant breath sounds in the same area and occasional superficial fine rales. No friction rub could be heard. The liver edge, which was palpable on deep inspiration just under the right costal margin, was somewhat tender. Heavy fist percussion over the liver elicited pain. The temperature was 100°F., the pulse 88, and the respirations 18.

HEPATIC COMPLICATIONS OF AMEBIASIS*

HARRY WARSHAWSKY, M D, † D E NOLAN, M D, ‡ AND WILLIAM ABRAMSON, M D §

DAYTON, OHIO

THE purpose of this paper is to invite attention to some of the bizarre and puzzling manifestations of amebiasis that have been encountered, with special reference to hepatic complications. Pitfalls in diagnosis may be easily avoided if the possibility of amebiasis is kept in mind. It should be remembered that dysentery is an infrequent manifestation of amebiasis. Even lesions in the large intestine are not invariably found on sigmoidoscopic examination. Therefore, despite the absence of a history of dysentery, amebiasis must be considered in the differential diagnosis of many bizarre clinical syndromes.

The disease is not restricted by geography or climate. Poor sanitation and poor hygiene are chiefly responsible for its spread. It is frequent in the southern states but is not rare in the northern ones. In 1933 the disease intruded itself into the national consciousness as a result of the outbreak of amebic dysentery at the Century of Progress Exposition in Chicago. At present, a far more serious source of dissemination has appeared in our work at this large hospital we are seeing ever-increasing numbers of returning service men affected with tropical diseases. Bomford,¹ in an article on chronic amebiasis in soldiers of the British Army, emphasizes the fact that awareness of this disease and its many manifestations results not only in early diagnosis but also in a reduction of the hazards of dissemination. In 1942 Faust² estimated the incidence of carriers to be 20 per cent of the total population. What effect the recent influx of a host of carriers will have on this already menacing number time alone will tell. In the Veterans Administration hospitals physicians are in a particularly favorable position to observe this disease and to check its spread by prompt diagnosis and adequate treatment. The large number of veterans of World War II who will pass through these hospitals within the succeeding months and years constitutes a challenge to the efficiency of the medical profession. The future will clearly show how effective the fight against amebiasis has been. A high index of suspicion is the keynote of early diagnosis.

The morphology of the parasite is well known, but differentiation of this pathogenic ameba from normal nonpathogenic inhabitants of the human

intestinal tract is difficult. The motile vegetative forms or trophozoites, which are invasive and are responsible for the pathologic changes characteristic of the disease, do not serve as a means of transmission. They are short lived outside the body and probably cannot survive passage through the stomach following ingestion of contaminated food. The cysts are the infecting agents, because they are resistant to marked changes in their environment. It is essential to realize that ordinary chlorination does not destroy the encysted forms, which at freezing temperatures can remain viable for weeks. The character of the stools determines the form of the parasites present. In the presence of diarrhea, it is exceptional to find anything but trophozoites. If the formed stools are passed, only cysts are usually found. Needless to say, careful stool examinations by experienced technicians are helpful in the diagnosis. It is reiterated, however, that the absence of the pathogen from the stools is not positive evidence that amebic infection is not present. Sigmoidoscopy should always be performed because the diagnosis of amebic colitis is frequently made from the gross appearance of the colonic ulcers, and in addition, the organism is often found in smears taken from the floor of these ulcers. It is not the purpose of this paper to outline diagnostic procedures, which are covered in standard texts.

Invasion of the submucosa of the wall of the colon may be followed by the entry of *Endamoeba histolytica* into radicles of the portal vein and metastasis of the infection to the liver. This is followed by amebic hepatitis or amebic abscess. Such abscesses may be single or multiple, acute or chronic. In an analysis of 1000 cases of amebic dysentery Payne³ found hepatitis to be present in over 50 per cent and liver abscess in almost 3 per cent, the latter figure is in close agreement with that of other investigators. — Craig⁴ observed liver abscesses in 5 per cent of 745 cases. The term "amebic hepatitis" is used to indicate the early phase of amebic hepatic disease before frank abscess can be diagnosed. Ochsner and DeBakey⁵ emphasize the differentiation of the two. Sodeman and Lewis⁶ stress the fact that it is impossible to be certain clinically that small single or multiple abscesses are not present during the early phase, when diagnosis and treatment are extremely important.

Multiple foci of necrosis may coalesce to form a single large abscess. Leukocytic infiltration of the wall occurs even in the absence of secondary bacterial infection. The most frequent seat of the
